peak [44.111, 112]. Figure 44.34 plots $I(L_3)/I(L_2)$ versus the Mn valence state for the reference data [44.112] and for the data from this MRAM study. Deduced from the correlation to the reference data, the valence state of Mn in Al_2O_3 is found to be around +2.2. Thus, Mn diffused into the Al_2O_3 layer and accumulated there in an oxidized state [44.60].

EELS Fine Edge to Study Interface Material. Figure 44.35 shows a HAADF STEM image of Al/WN_x interface with an EELS elemental line scan [44.50]. A nitrogen-rich interface is observed in the line scan profile. The interface is also observable in the STEM image. From the elemental profile, it is difficult to identify the phase of the interface material. The EELS fine edge structure can be strongly affected by chemical bonding variations. This fine structure allows us to probe the information beyond elemental identification. Figure 44.36 shows a comparison of $\text{Al}-L_{2,3}$ edge for the spectra from interface location and standard samples. The major difference in the fine edge structures of

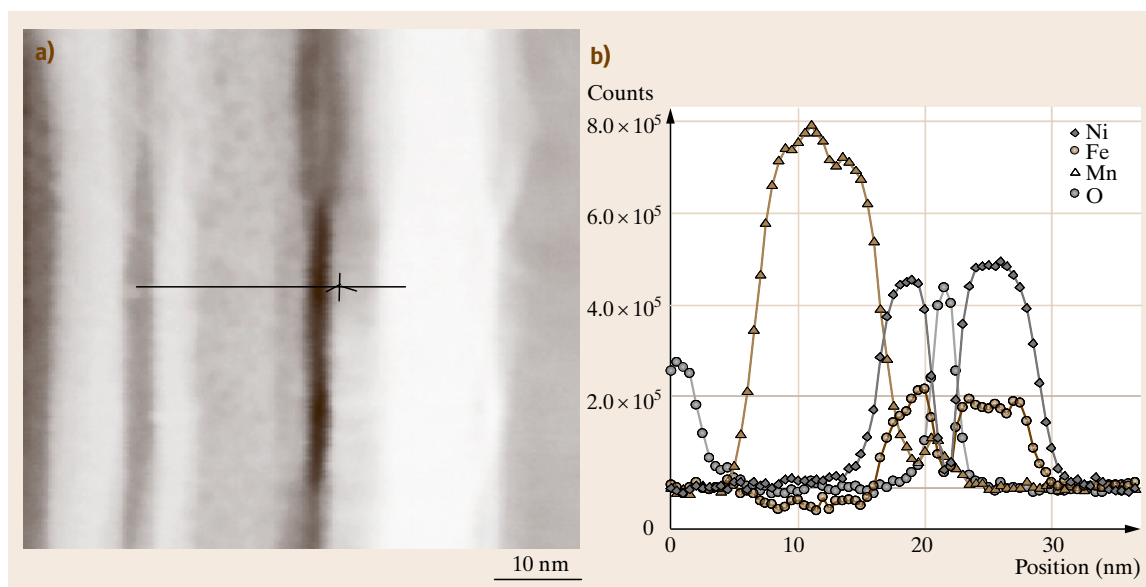

Fig. 44.32a,b EELS line scan across a MRAM stack. (a) STEM image showing the features and the scan line location. (b) Elemental profiles along the scan line as detected by EELS

Fig. 44.33 Comparison of manganese $L_{2,3}$ edge spectra from Mn layer and from Al_2O_3 layer. The baselines are used for calculating the $L_3 : L_2$ ratio

Al and AlN is indicated by the three arrows (a, b, and c). Here we observe that the spectrum from interface is very similar to that of AlN, except for the small shoulder indicated by arrow a. In comparison with that of Al metal, we find this extra shoulder is most likely caused by overlapping Al metal. This analysis is further supported by comparison of EELS in the low-loss region

Fig. 44.34 A plot of white line intensity ratio $I(L_3)/I(L_2)$ versus the valence state of Mn (after [44.60])

(Fig. 44.37). In Fig. 44.37, we can see the distinguishing features for Al and AlN. The low-loss spectrum from the interface again resembles the summation of Al and AlN spectra. Thus, by combining the information from EELS line scan (elemental identification) and the fine edge structure comparison, we conclude that the interface layer between Al/ WN_x is AlN_x . The existence of Al metal at the interface is mostly likely caused by overlapping.

Fig. 44.38a,b Comparison of conventional HREM (a) and energy-filtered HREM (b)

EFTEM Applications

EFTEM to Image Thick Sample. Figure 44.38 shows a conventional HREM image of a crystalline HfO₂ layer in contact with Si and TiN. Because the sample is not sufficiently thin, part of the blurring of the HREM image is due to inelastic electrons. Figure 44.38b shows an energy-filtered (zero-loss) image of the same feature. The imaging improvement by energy filtering is obvious through the lattice images of the TiN, HfO₂, and Si regions.

EFTEM to Map Elemental Distributions. For many elements, EFTEM enables fast and distinctive elemental mapping. Figure 44.39 shows a series of elemental maps of a defect in a semiconductor device. The chemical distribution is clearly revealed. Compared with other elemental mapping techniques such as EDS elemental mapping, EFTEM elemental mapping can achieve much higher spatial resolution.

EFTEM to Enhance Contrast. EFTEM can be used to enhance contrast in situations when TEM would show low contrast. An example is given in Fig. 44.40. As indicated by the arrow, the Si low-loss image (using the Si plasma peak at about 15 eV) clearly reveals Si particles where the bright-field TEM image shows low or no contrast.

EFTEM to Reduce Diffraction Contrast. EFTEM can often be used as an alternative method to Z-contrast STEM to reduce diffraction contrast. This can be critical in situations such as electron tomography of crystalline materials where orientation-dependent contrast is to be avoided [44.114]. Most EFTEM, except zero-loss imaging, offers a certain reduction of diffraction contrast. The diffraction contrast reduction can be seen in both Figs. 44.38 and 44.39. EFTEM offers a wide variety of energy-filtering controls. Some EFTEM methods, such as jump-ratio imaging [44.114]

Fig. 44.39 Elemental maps of a defect in a semiconductor device obtained by EFTEM

Fig. 44.40 (a) TEM image. (b) Si low-loss image. The arrow indicates equivalent area in the two images

Fig. 44.41a,b The result of diffraction contrast reduction by EFTEM. (a) TEM bright-field image; (b) energy-filtered 74 eV low-loss (energy window width = 10 eV, centered at 74 eV) image (after [44.50])

(dividing the post-edge image by the pre-edge image) and certain low-loss-region imaging [44.115], are more effective in reducing diffraction contrast. Figure 44.41 shows a comparison of a **TEM** and the 74 eV low-loss

image. The prominent diffraction contrast in polycrystalline Si is effectively suppressed in the 74 eV low-loss image, where the majority contrast is due to material difference.

44.3 Concluding Remarks: Current Application Status and Development

As an efficient technique to explore the microstructure of various materials, **TEM** has been extensively applied in both the research and industrial fields. Through observation and analysis of structural features and defects, it plays a key role in the evaluation of materials quality, the investigation of defect formation mechanisms, and the correlation between processing and microstructural properties.

Conventional **TEM** techniques such as diffraction-contrast imaging, selected-area diffraction, convergent-beam electron diffraction, and large-angle convergent-beam electron diffraction are extensively used to characterize defects in both bulk and epitaxially grown crystals. Examples of such application include the study of threading dislocation density reduction in wurtzite-type epilayers, defects produced by composition variations in semiconductor alloys, and strain relaxation and dislocation behavior in strained Si/SiGe epilayers. LACBED has the advantage of being able to characterize most types of crystal defect (point defects, perfect and partial dislocations, stacking faults, antiphase boundaries, and grain boundaries). In addition to the aforementioned basic functions, many techniques, such as **EDS**, **EELS**, **STEM**, **EFTEM**, holography, and tomography, have been incorporated into the **TEM** system. The modern **TEM** system is a high-resolution probe with extensive capabilities for exploration of the internal structure of various materials.

In recent years, **TEM** has become even more important, as the structural dimensions in many research and industrial applications are rapidly approaching the nanometer scale. The high-resolution **TEM/STEM** with various analytical functions has become an indispensable tool for nanoscale defect analyses. Take the semiconductor industry as an example; the trend for ever-shrinking device dimension has demanded that defect analyses be localized to the nanometer scale. This has led to increased use of the **TEM** as an integral part of process development and failure analysis. Examples include distributions and density of crystalline defects at the thin-film metallization-silicon substrate interface, defect formation and involvement

during dopant implantation and thermal treatments, and measurement of local strains in the critical channel region of fully processed devices. The powerful sample preparation technique, **FIB**, providing accurate specimen thickness control over large area as well as being highly site specific, is especially useful in nanoscale devices. In addition to its importance in imaging nanoscale microstructures, **TEM** is also the only technique that can produce high count rates in diffraction patterns from individual nanotubes or other nanostructures. Capable of revealing small lattice-parameter changes, **CBED** strain analysis finds its application in the semiconductor industry in analyzing strain variations within device substrates. Furthermore, with the advances of nanotechnology, electron tomography has found an increasingly important role in the physical sciences. For materials with complex nanoscale structures, electron tomography offers a promising solution to overcome the difficulties caused by sample thickness limitations.

The progress of materials analysis by **TEM** largely relies on the advances of instrumentation. Various technologies have been applied to improve the spatial resolution of **TEM/STEM** imaging and the energy resolution of **EELS**. Recent progress includes lens aberration correctors to improve **TEM** and **STEM** resolution and monochromators for reducing energy spread of the electron beam. With the help of these new technologies, atomic-scale defect analysis will become more precise and convenient. The use of aberration correctors allows the relaxation of the tight spacing around the specimen. One benefit is naturally the easier accommodation of in situ apparatus within the **TEM**. The in situ experiments of interest to the readers may include in situ **TEM** observation of defects under the influence of mechanical and/or electrical stress. Meanwhile, the quality of electron microdiffraction has been greatly improved with the availability of energy-filtered imaging, field-emission guns, liquid-helium-cooled sample stages, charge-coupled device (**CCD**) cameras, monochromators, aberration correctors, and energy-loss spectrometers with parallel detec-

tion, together with much faster computers. It has now become possible to measure low-order structure factors from crystals of known structure using the quantitative convergent-beam diffraction method with accuracy equal to or better than that of the x-ray Pendellösung method. The well-developed analytical capabilities (EDS, EELS) of TEM provide compositional information with spatial resolution in the nanometer and subnanometer range. Combined with structural information from high-resolution phase-contrast imaging, such capabilities make TEM an indispensable tool for the development and application of new materials in the fields of semiconductors, ultrafine-grain materials or thin films. Energy-filtering TEM (EFTEM) has proven to be the key tool for nano-analytical applications, since it uses the rich information provided by the energy-loss spectrum in a spatially resolved manner with short acquisition times.

As with any analytical tools, TEM has its own limitations. The most notable ones are as follows:

1. TEM observation is very localized. It is not a suitable way for large-scale sampling.

2. Due to dynamical scattering, quantitative diffraction analysis can be difficult compared with x-ray and neutron diffraction.
3. TEM sample preparation is destructive.
4. There are possible surface effects, which become increasingly important with reduced sample thickness.
5. Electron-beam damage can be significant in some situations.
6. Structural defects can be generated or changed by sample preparation and electron-beam irradiation.

New developments in TEM instruments have enabled major improvements on two fronts: the ability to see ever smaller things and the ability to see the *unseeable*. Various contrasts with TEM/STEM have enabled various structural, defect, and chemical analysis with resolution as high as 0.1 nm. With improvements on both theoretical and instrumental fronts, we expect new advances in the field of transmission electron microscopy. At the same time, we may say that TEM itself has matured to be a premier research tool in materials analysis.

45. Electron Paramagnetic Resonance Characterization of Point Defects

Mary E. Zvanut

Electron paramagnetic resonance (EPR) spectroscopy identifies, counts, and monitors point defects in a wide variety of materials. Unfortunately, this powerful tool has faded from the literature in recent years. The present trend away from fundamental studies and towards technological challenges, and the need for fast diagnostic tools for use during and after materials growth has weakened the popularity of magnetic resonance tools. While admittedly the use of EPR in industrial laboratories for routine materials characterization is limited, EPR spectroscopy can be, and has been, successfully used to provide reams of information directly relevant to technologically significant materials.

The interpretation of EPR spectra involves an understanding of basic quantum mechanics and a reasonable investment of time. Once a defect is identified, however, the spectra may be used as a fingerprint that can be used in additional studies addressing the chemical kinetics, charge transport, and electronic energies of the defect and surrounding lattice. Numerous examples are provided in this chapter. In addition, the fundamental information extracted from EPR analysis should not be forgotten. Perhaps knowing the distribution of spin states about the core of a defect will not expedite the production of material X for use as device Y, but it may provide the seed of knowledge with which to build the 21st century's technological revolution. We must remember that the basic understanding of semiconductors developed in the middle of the last century

spawned the solid-state transistor, which unquestionably produced the computer revolution in the latter half of the 20th century.

This chapter will acquaint the reader with the fundamental methods used to interpret EPR data and summarize many different experiments which illustrate the applicability of the technique to important materials issues.

Electron paramagnetic resonance (EPR), or electron spin resonance (ESR), provides fundamental chemical and structural information about a point defect. For example, by detecting the unpaired (paramagnetic) electron on the nitrogen donor in SiC, EPR results show that

nitrogen substitutes for carbon and that the electron-nuclear hyperfine interaction differs by a factor of ten for the different symmetry sites in the 4H- and 6H-SiC polytypes. The total number of uncompensated nitrogen donors may also be determined. Note that EPR senses

specific charge states of the defect. For instance, in the case of nitrogen in SiC only neutral nitrogen with the donor electron *on* the nucleus is detected. Also, it is important to realize that EPR probes the ground state of a defect; thereby providing information about the *as-grown*, unperturbed defect. Illumination or heat may be used during a measurement to alter the charge state or produce the excited state, providing additional information. Ultimately, the electron wavefunction overlap with the core nucleus and surrounding neighbors may be determined. While this last bit of information may not be pertinent to most immediate applications, taken together the data paint a thorough picture of a specific center, enabling additional knowledge to be gleaned from the same defect in similar materials as well as other defects in the same host.

Having read other chapters in this Handbook, the reader may wonder how EPR compares with other techniques. EPR does *not* provide information about the lattice symmetry like x-ray diffraction or the overall chemical composition of the material as can be obtained from energy-dispersive x-ray analysis. Most importantly, the concentration of defects is not directly obtained from an EPR spectrum. The total number of a specific defect can be estimated, sometimes within a factor of two, but the distribution of centers is not sensed by magnetic resonance. Therefore, any concentration measurement must be inferred from etching studies or measurements of different sized samples. Finally, many readers may be familiar with nuclear magnetic resonance (NMR). Although the physical principle of NMR and EPR are the same, implementation of the techniques is entirely different, as a reader familiar with NMR will realize when they read this chapter. Unlike NMR, EPR has never been successfully adapted for scanning, as has NMR, where the technique has become the basis of magnetic resonance imaging. Whereas many of the methods discussed in this text provide the electronic or chemical identification of a defect, EPR can provide a complete picture – after great investment of time and analysis. Thus, while EPR provides a great deal of information, it cannot be used as a substitute for conventional characterization methods used routinely on a large volume of material. Rather, the technique provides many important details

about point defects that are not detectable by other means.

As with any technique, correlation with other experimental tools augments the information provided. The use of optical excitation, for example, sometimes enables one to extract defect levels (ionization energies) or probe the excited state of a defect. In addition, comparison of EPR spectra with optical absorption studies has enabled the identification of many optical absorption bands and the calculation of optical cross sections. Electrical measurements in tandem with EPR studies have also produced important scientific and technological information about trapping centers in electronic devices. In principle, comparison with secondary-ion mass spectroscopy (SIMS) or glow-discharge mass spectroscopy (GDMS) data could provide the fraction of impurities in a particular charge state or located at a specific lattice site.

Before closing this Introduction, the reader should be made aware that EPR measurements were first recorded in 1945, and have permeated the literature for the past 60 years, covering chemistry, biology, physics, and engineering journals. In addition to the defects in materials discussed here, the technique is widely used to study free radicals in solution and biological species. There is active work detecting the many complicated structures responsible for diseases, as well as the more benign moieties responsible for life. Within the framework of materials, there are studies in nanomaterials, amorphous solids, and interfaces, some of which will be mentioned in this chapter. Many texts and articles are available that cover the application of EPR to the multitude of fields mentioned [45.1–6].

The chapter will begin with a review of the EPR instrumentation, briefly explaining the significant parts of the spectrometer and detection system. This will be followed by a section outlining the heart of the analysis using examples to illustrate the many features extracted from EPR spectra. The next two sections will cover the scope of the technique as it applies to defects in solids and the typical correlation experiments involving EPR. Finally, the last section will summarize the material presented and outline the different types of magnetic resonance techniques amenable to the study of defects in materials.

45.1 Electronic Paramagnetic Resonance

Electron paramagnetic resonance is based on the absorption of energy between spin states induced by the

presence of an applied magnetic field [45.1, 7, 8]. In order to appreciate the technical aspects of the exper-

Fig. 45.1 Energy levels for a spin- $\frac{1}{2}$ electron in zero magnetic field (left) and nonzero applied field (right). The vertical arrows represent the spin of the electron; m_s is the magnetic spin quantum number

iment, one must understand the following. If there were no internal magnetic fields affecting the defect and if the defect contains a single unpaired electron (like that of a donor in a semiconductor), the absorbed energy is

$$h\nu = \Delta E = \mu_b g B, \quad (45.1)$$

where h is Planck's constant, ν is the frequency of the absorbed radiation, μ_b is the Bohr magneton, and B is the applied magnetic field. The term $\mu_b g B$ is the energy difference between the spin states shown in Fig. 45.1. We leave discussion of g until the next section. The point here is that, if you place your sample in a magnetic field while illuminating with different frequency radiation, you should be able to adjust the incident photon energy until absorption is detected, similar to an optical absorption measurement. However, because $g \approx 2$ and convenient magnetic fields are on the order of Tesla, ν is typically in the microwave region. Unfortunately, microwaves are not conveniently manipulated like optical photons; thus the actual situation requires placing a sample in a fixed microwave field and applying a series of magnetic fields. One then searches for the field that produces microwave absorption. The energy levels for the single unpaired electron in an applied magnetic field are shown schematically in Fig. 45.1 and a typical spectrum illustrating detection of the EPR signal is shown in Fig. 45.2.

The instrumentation for EPR was developed in the 1950s, and little has changed except for the addition of more sophisticated detection circuitry and data-acquisition electronics. Figure 45.3 illustrates the basic experimental setup. The spectrometer consists of the klystron or Gunn diode used to produce the microwave radiation, microwave bridge for setting the desired power, waveguides which transmit the radiation to the sample, and cavity resonator in which a particular mode of the microwave is stored. As stated above,

Fig. 45.2 Typical EPR spectrum illustrating the derivative line shape and zero-crossing B_z where the g value is calculated. The spectrum was obtained from 4H-SiC at 4 K with the magnetic field parallel to the c -axis of the crystal. The dotted line represents zero intensity

wavelengths in the microwave region are not easily varied, so a fixed frequency of 10 GHz is commonly used. The dimensions of the cavity establish a specific mode of the microwave frequency, in a similar way that a specific length of string determines the possible modes of a mechanical wave. The microwave energy stored in the standing wave is ultimately the energy absorbed by the sample when the resonance condition (45.1) is fulfilled. In order to produce an EPR signal, two more features must be understood: coupling of the microwaves in the

Fig. 45.3 Schematic diagram of EPR instrumentation; see text for description of the purpose for each component

cavity to the detection circuitry and the generation of the applied magnetic field. The former employs standard microwave electronics, as is discussed in detail in many texts [45.7]. The latter simply uses a standard magnet power supply and electromagnet that communicate with the spectrometer to set the magnetic field amplitude and ramp rate.

The instrumentation described above leads to the detection of microwave absorption at defects. However,

the reader familiar with spectroscopy will recognize that the spectrum in Fig. 45.2 is not a simple absorption; rather it reflects the derivative of the absorption. In order to detect the small amount of paramagnetic defects typical of most materials, a type of phase-sensitive detection is employed. In practice, an oscillating magnetic field is superimposed on the ramped field and the change in the absorption is detected. This AC detection method produces the derivative spectrum shown in Fig. 45.2.

45.2 EPR Analysis

The theory of EPR rests on the concept of the *spin Hamiltonian*, which sums all of the energy sources affecting the electron dipole moment at the defect. The most obvious contribution comes from the applied magnetic field, but there are many others, some of which can be much larger than the effect of the applied field. The only ones considered here are the nuclear magnetic field and the spin–spin interactions. Below, each effect is treated individually and is accompanied by examples reflecting the type of interaction described.

45.2.1 Zeeman Effect

If there were no internal fields affecting the defect, the absorbed energy may be described by the interaction of the applied magnetic field B with the electron spin at the defect. The appropriate Hamiltonian is the Zeeman term

$$H = \mu_b \mathbf{S} \cdot \mathbf{g} \cdot \mathbf{B}, \quad (45.2)$$

where μ_b is the Bohr magneton, \mathbf{S} is the total spin of the electron, and \mathbf{B} is the applied magnetic field. The \mathbf{g} -tensor is related to the proportionality factor between the quantized electron magnetic dipole moment and total angular momentum. In EPR \mathbf{g} takes on a significant role as will be seen later. Assuming simple spin- $\frac{1}{2}$ wavefunctions, $|\frac{1}{2}, \frac{1}{2}\rangle, |\frac{1}{2}, -\frac{1}{2}\rangle$, the energy solutions are

$$E = \mu_b g B m_s, \quad (45.3)$$

where m_s is the z -component of the spin angular momentum $\pm\frac{1}{2}$. (The “bra-ket” notation is a standard method for denoting the wavefunction of the electron where here we use only the spin part: $|s, m_s\rangle$ where s is the electron spin and m_s is the magnetic spin quantum number. In general, the spin wavefunction for a paramagnetic electron at a defect may be a linear combination of s, m_s states.) The energy difference between the two m_s states, $\mu_b g B \Delta m_s$, is $\mu_b g B$ as seen in (45.1). The two spin levels are illustrated in Fig. 45.1 for a fixed

value of magnetic field. Experimentally, the g -value is extracted from the magnetic field at which the intensity of the spectrum crosses zero intensity, as is indicated in Fig. 45.2 by B_z . In the simple case of a single electron free from the influence of any other magnetic fields, the g -value is the Lande free electron value. In a crystal, g is shifted by an amount that depends on the local environment of the defect. The shift is generally caused by a small amount of angular momentum that is not included in (45.2), but enters the theory as a perturbation and is incorporated into the g -value [45.1, 7–9]. Thus, each defect has a characteristic g -tensor determined by

Fig. 45.4 EPR spectra illustrating the shift in the g -value as the mass of the central nucleus increases. Data was obtained from SiGe (brown) and SiC (grey) at 4 K. The elemental labeling (Ge, Si and C) indicates the central nuclei of the defects represented by the signal highlighted with an arrow. The vertical dashed line represents the g -value of a free electron. Note that the x -axis decreases to the right

its surroundings. Figure 45.4 illustrates the effect of the nearest neighbors on the g shift for a simple *dangling bond* center on a carbon atom in SiC (spectrum labeled “C”), silicon atom (Si) in SiGe and germanium (Ge) atom in SiGe (black spectrum). Here the x -axis is interpreted in terms of g through (45.1) with ΔE as the microwave energy; the free electron g -value, indicated by the dashed line, is used to approximate g for the defects. The EPR signal shifts to lower magnetic field (higher g) as the atomic number of the atom increases. Although by no means a hard rule, the shift is typical of this simple type of defect and reflects the change in the spin-orbit coupling parameter with increasing atomic number [45.9].

In the Zeeman term of (45.2), \mathbf{g} is a tensor that incorporates the angular dependence of the interaction between the magnetic field and electron spin angular momentum. Whereas the hyperfine tensor discussed next provides chemical information about the point defect, the \mathbf{g} -tensor provides structural details because it reflects the defect symmetry. The tensor is obtained from the g -value measured at each orientation of the sample with respect to the incident magnetic field. The interpretation of (45.2) in terms of the symmetry of \mathbf{g} and the method used to extract this information is described in many texts. Suffice it to say that in general \mathbf{g} may be written as

$$g^2 = g_X^2 \cos^2 \theta_X + g_Y^2 \cos^2 \theta_Y + g_Z^2 \cos^2 \theta_Z, \quad (45.4)$$

where θ_i is the angle between the i -th ($i = X, Y$, and Z) axes of the defect and the applied magnetic field. It is important to realize that X, Y , and Z are *not* necessarily the x -, y -, and z -axes of the crystal structure. Furthermore, the orientation of the defect axes with respect to, for example, the horizontal distance between the poles of the magnet, is not generally known. The procedure for extracting X, Y , and Z from angular measurements with respect to the known crystal axes is thoroughly described in [45.1].

To illustrate, consider a defect in a hexagonal material where measurements are made in a plane containing the c -axis. Measuring B_z for a series of spectra, calculating g , and plotting against the angle between B and the c -axis can produce the data shown in Fig. 45.5. The filled squares represent the g -values of the Mg-related acceptor signal in GaN and the solid line is a fit to the equation

$$g^2 = g_{\parallel}^2 \cos^2 \theta + g_{\perp}^2 \sin^2 \theta \quad (45.5)$$

where θ is the angle between the magnetic field and the principle axis of the defect. Note that (45.5) is a special case of (45.4) where $g_X = g_Y = g_{\perp}$ and $g_Z = g_{\parallel}$.

Fig. 45.5 Plot of the g -values calculated from EPR spectra obtained with the magnetic field in the plane of the c -axis and measured at selected angles with respect to the c -axis of a GaN film. The data (filled squares) were obtained from the Mg-related acceptor signal at 4 K. The fit to (45.5) is illustrated by the solid line

In the case of the Mg acceptor, θ_i is the same as the laboratory angle measured between B and the c -axis because the principle axis turns out to be the c -axis. A fit of (45.5) to the data in Fig. 45.5 shows that $g_{\parallel} = 2.096$ and $g_{\perp} = 2.008$. Although the specific values of g_{\parallel} and g_{\perp} provide some information, the main conclusion obtained from these data is the determination of the symmetry of the center. A defect exhibiting the angular dependence of (45.5) is said to have axial symmetry. In this case, the magnesium-related acceptor has axial symmetry about the c -axis. Confirmation of the axial symmetry requires rotation about two additional crystal axes. Specifically, rotation about the axis of symmetry, c -axis, should reveal spectra that do not depend on rotation angle. Unfortunately, this has not yet been possible for GaN because most samples are films grown in a predetermined orientation. Figure 45.6 shows measurements of the g -shift for the boron acceptor in bulk 6H-SiC, where results obtained from three rotation planes are plotted [45.10]. The Greek letters η , ξ , and ζ designate the high-symmetry cubic directions $[1\bar{1}0]$, $[112]$, and $[\bar{1}\bar{1}0]$, respectively. The sets of lines in each orientation plane represent data from the three different symmetry sites in 6H-SiC and the four possible bonding directions. Note that in the last panel, when the sample is rotated about the c -axis, one set of data forms a horizontal line. These results were obtained from the

Fig. 45.6 The shift of the g -value from the free electron value when an EPR spectrum is measured in the rotation planes indicated above each panel in the graph: $(11\bar{2}0)$, $(10\bar{1}0)$, and (0001) . The vertical lines indicate the crystal directions in the cubic system: η , $[1\bar{1}0]$; ξ , $[112]$; ζ , $[\bar{1}\bar{1}0]$. Data were obtained from the shallow boron acceptor in 6H-SiC at 4 K (after [45.10], © IOP 1998)

hexagonal site where the defect axis is oriented along the c -axis of the crystal. When the data for this site is followed into the other two panels, the angular pattern illustrated in Fig. 45.5 is revealed, as expected for a site with axial symmetry about the c -axis.

At this point, it is not at all clear how the chemical identity of a defect is determined. One might guess that there are calculations relating the \mathbf{g} -tensor to specific types of point defects. Unfortunately, the \mathbf{g} -tensor is difficult to calculate accurately because the wavefunction must be known over the entire crystal space, a situation that is difficult to achieve using even the most powerful computers. However, the story does not end with the Zeeman term. The two remaining terms to be discussed in this chapter, the nuclear hyperfine and the fine-structure terms, provide a great deal more information about the chemical, structural, and electronic state of the defect.

45.2.2 Nuclear Hyperfine Interaction

When nuclei of nonzero spin are sufficiently close to a paramagnetic defect, an additional magnetic field must be considered, that of the nuclear magnetic moment. The term is written as

$$H = \sum_j \mathbf{S} \cdot \mathbf{A} \cdot \mathbf{I}_j, \quad (45.6)$$

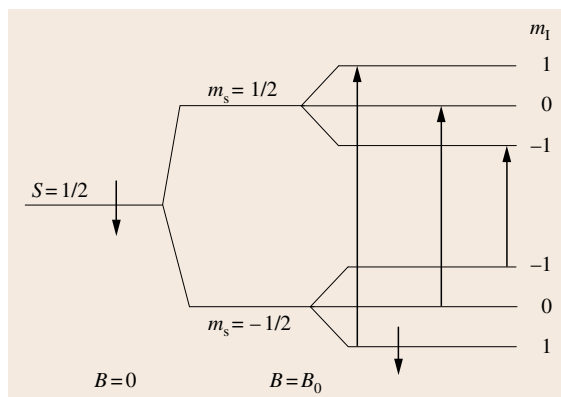

Fig. 45.7 Energy-level diagram from a spin- $\frac{1}{2}$ electron: in zero magnetic field (*leftmost*); applied field in absence of any other magnetic fields (*middle*); in the presence of a nuclear magnetic field (*rightmost*). m_I is the magnetic spin quantum number for the nucleus. The downward arrow represents the electron spin; the upward arrows represent allowed transitions

where \mathbf{A} is the hyperfine tensor and \mathbf{I} is the spin of the j -th nucleus surrounding the defect. This local nuclear magnetic field splits the electronic levels shown in Fig. 45.1, so that the situation becomes that shown in Fig. 45.7. Here m_I is the nuclear magnetic quantum number analogous to m_s . The size of the separation between the m_I levels A depends on the strength of the interaction. The nuclear hyperfine interaction may be different for the same defect in different materials as well as for different centers in the same material. However, I is a property of a given nucleus, so that it can be used to distinguish different defects, practically independent of the host. Specifically, the number of nuclear hyperfine lines originating from transitions between the different levels in Fig. 45.7 is proportional to I , thereby giving us the first clue into the chemical identity of the center. Since the selection rule allows only transitions with $\Delta m_s = \pm 1$ and $\Delta m_I = 0$ the Zeeman EPR line will divide into $2I + 1$ lines as shown by the upward arrows in Fig. 45.7. All the hyperfine lines will have the same intensity, and they will be spaced equally from the Zeeman EPR line. Because the intensity of a transition depends on the total number of defects causing the absorption, the isotopic abundance of the nonzero spin nuclei and the number of like nuclei determine the ratio of hyperfine line intensity to the intensity of the total spectrum. (Intensity here refers to the total integrated intensity of the hyperfine lines and the spectrum.)

Two examples are discussed to provide an understanding of the nuclear hyperfine portion of EPR spectra: the shallow nitrogen donor in SiC and the positively charged carbon vacancy in SiC. The former illustrates a 100% abundant nuclear spin entity and the latter is a case where the nuclear spin is much less than 100%. Although both examples are defects in SiC, the situations are quite general. The only effect of the environment is the strength and symmetry of the interaction, neither of which is critical to the basic understanding of the hyperfine term.

Figure 45.8 shows the characteristic EPR fingerprint of isolated N atoms in SiC: three evenly spaced lines of equal intensity. (Nitrogen has nuclear spin 1 and is 100% abundant.) The vertical arrows point to the three hyperfine lines arising from the interaction between the magnetic field and the nitrogen nuclei situated at the cubic sites in 4H-SiC. The large line marked with an arrow is a distorted spectrum of nitrogen on the hexagonal site in SiC. This site exhibits the three hyperfine lines as shown for the cubic site when different EPR parameters are used. Semiclassically, one could picture the origin of the three lines as follows: the Zeeman energy at which the paramagnetic electron absorbs the incident radiation E_z is shifted by the interaction between the hyperfine interaction between the electron and magnetic nucleus. Since almost all nitrogen atoms have a nuclear spin of 1, the Zeeman energy at each nitrogen has equal probability of being lowered ($m_I = -1$), increased ($m_I = +1$) or unaffected ($m_I = 0$), depending

Fig. 45.8 EPR spectrum of nitrogen in 6H-SiC obtained at 30 K with the magnetic field parallel to the c -axis

on the relative orientations of the electron and nuclear magnetic dipole moments. Thus, three lines of equal intensity are produced: one representing $E_z - E_{\text{hf}}$, one $E_z + E_{\text{hf}}$, and one E_z , where E_{hf} is the hyperfine interaction energy. The magnetic field separation between the lines is proportional to E_{hf} . The hyperfine parameter A is proportional to this energy, and is often quoted in terms of magnetic field units T through the conversion A/gB , where g is the g -value for the spectrum and B_z is the magnetic field separation between the adjacent lines. The g -value is obtained from the average B_z of the outer two lines, or in this case, B_z of the central line. Exhaustive analysis of the nitrogen spectrum may be found in numerous papers [45.11, 12].

From the above, it should be apparent that observation of the nuclear hyperfine lines is the key to determining the chemical origin of an EPR center. Not all impurities have isotopes with 100% abundant nonzero nuclear spin. For example, only 4.5% of all Si atoms (^{29}Si) and a mere 1.1% of carbon atoms (^{13}C) are spin $\frac{1}{2}$. Therefore, any intrinsic defect in SiC has a very low probability of being situated near a nucleus of nonzero spin. In these cases, the spectrum consists of a strong Zeeman line due to defects involving spin-zero Si and C nuclei, and pairs of equally spaced smaller lines due to the very few defects involving spin- $\frac{1}{2}$ Si and C nuclei. Figure 45.9 shows an EPR measurement of V_c^+ . The satellite lines A and B arise from the spin- $\frac{1}{2}$ nearest-neighbor Si nuclei. The ratio of the relative integrated intensity of set A to the intensity of the entire spectrum is about 5% and that for set B is 15%. The outer set is attributed to those centers for which the spin- $\frac{1}{2}$ nucleus is located along the c -axis; the inner set to those in which any one of the three remaining Si neighbors is spin $\frac{1}{2}$. The darkest circle in the sketch in the upper right corner of the figure represents the single *unique* axial silicon (A lines), while the three lighter circles represent the other nearest neighbors (B lines). In summary, detection of two sets of hyperfine lines with intensity equivalent to interactions with four Si atoms distinguished by two different energies paints a picture of a carbon vacancy slightly distorted along the c -axis. The positive charge states is determined primarily from theoretical calculations as is discussed later. A complete analysis of this center along with that of the V_c^+ located on the other symmetry site of 4H-SiC is discussed in [45.13].

Hyperfine lines of low-atomic-abundance nuclear spins are often difficult to detect, particularly if the number of defects is also small. This is often the case for Si- and C-based semiconductors, where defect densities are below 10^{16} cm^{-3} and the abundance of the nonzero

Fig. 45.9 EPR spectrum of the positively charged carbon vacancy in 4H-SiC obtained at 4 K with the magnetic field parallel to the c -axis. The lines marked A and B are the hyperfine lines due to neighboring Si atoms. The model in the upper-right corner shows the four Si neighbors of the carbon vacancy, where the brown circles produce the B lines and the dark gray circle produces the A lines. The light gray circle represents the carbon vacancy

spin isotopes is less than a few percent. In these cases, isotopic enrichment allows for enhanced hyperfine detection. For instance, recently isotopic enrichment was used to enhance the hyperfine of Se impurities in Si and intrinsic defects in SiGe alloys [45.14, 15].

The angular dependence of the hyperfine interaction allows one to map out the local spin density, or effectively determine the wavefunction of the paramagnetic electron. To understand this one has to appreciate that the type of spatial wavefunction will determine the relative directions of the electron–nuclear dipole coupling. Any orbital with $L > 0$ will be directionally dependent and therefore produce an angular-dependent hyperfine interaction. For example, a p_z -shell electron will have lobes along a specific axis, so that, if one measured an EPR signal along this axis, the hyperfine separation would be different from that measured along any other direction. Perhaps the more illuminating example is to consider $L = 0$, or an s -shell electron. Here, no angular dependence would be expected and the hyperfine parameter A should be isotropic, as is the case of phosphorus in Si. In many materials, a paramagnetic electron is a hybrid orbital containing contributions from s -, p -, and sometimes higher L -states. The separation be-

tween the hyperfine lines of nitrogen in Fig. 45.8 exhibit a small angular dependence. Contributions from s -like and p -like orbitals are deconvolved so that the percentage of the wavefunction that is s -like and p -like are determined. For the nearly isotropic nitrogen donor spectrum in 4H-SiC on the cubic site, the wavefunction at the impurity is found to be almost entirely s -like with less than 1% p -character [45.12]. The calculation of the amount of s - and p -character from angular-dependent hyperfine is straightforward and may be found in many texts [45.1]. Although not directly applicable to routine materials characterization, this type of information is extremely helpful to theorists calculating the strength of the hyperfine interaction because it provides a realistic starting function for determination of the hyperfine energies. It is these energies that refine the picture of the defect, particularly those involving nuclear spins common to many elements.

The nearest neighbors may not be the only nuclei contributing to the EPR spectra of a specific defect. When more distance neighbors are sensed, they often show up as sets of satellite lines more closely spaced than those of the nearest neighbors. For example, the pair of lines adjacent to the central line of the V_c^+ spectrum in Fig. 45.9 represents contributions from next-nearest-neighbor carbon atoms. Their intensity reflects the fact that any one of the 12 next nearest neighbors may be a ^{13}C nucleus. It should be pointed out that the analysis can eventually provide the probability that the paramagnetic electron resides on any one of the neighbors, effectively mapping out the spin density in the vicinity of the defect.

Theoretical Calculations of Hyperfine

As with any spectroscopic technique the experimental results may be compared with theory to extract additional information about the defect. In some cases, comparison with theory is the only means to interpret the EPR data in terms of a specific defect because the nuclear hyperfine is not detectable or is ambiguous. Luckily, unlike the g -tensor, the A -tensor is sensitive to at most the second or third nearest neighbors so that accurate calculations are feasible. Hyperfine calculations are particularly powerful tools to determine the defect structure because the strength of the nuclear spin–electron spin interaction is sensitive to the orientation and charge states of the environment. The entire A -tensor for different types of defects may often be predicted from density functional theory and the local spin-density approximation. The results produce an enormous amount of points that can be compared

with experimental data, thus reinforcing the interpretation of the data in terms of a specific defect structure. For example, the **A**-tensor for the positively charged carbon vacancy discussed above was calculated for the defect located at different symmetry sites of the two different polytypes of SiC (4H and 6H), as well as for different charge states [45.16]. The **A**-tensor was also extracted from the complete angular dependence of the EPR spectrum. Comparison of the two results showed that centers known as EI5 and EI6 are V_c^+ located at the hexagonal and cubic sites, respectively [45.13]. Similar comparison between theory and experiment revealed the spectra for HEI1 to be due to the negatively charged carbon vacancy [45.17]. Of course, not all defects in all materials are amenable to reasonable calculation. A large impurity atom and a low degree of symmetry can overwhelm the computational power of even the most modern computers. Nevertheless, comparison of EPR spectra to theoretical calculations of the nuclear hyperfine tensor has enabled the description of countless defects in innumerable types of materials.

To summarize, identification of nuclear hyperfine lines in EPR spectra is critical to determining the chemical origin of the center. The lines have the following characteristics:

1. Nearly equal intensity
2. Nearly equal separation and/or separated equally from the Zeeman line
3. The number of lines is $2I + 1$.

Also, all the lines should exhibit the same dependence on microwave power because they represent the same physical entity. Once the nuclear spin (I) is determined from the spectra, the possible types of nuclei contributing to the spectrum may be determined. Knowledge of the material composition and growth conditions often refines the type of nuclei expected to be involved in the defect. The angular dependence provides the basic components of the wavefunction, which can be used in theoretical calculations to determine the strength of the hyperfine interaction for different defect structures and charge states. Finally, comparison of the theoretically calculated **A**-tensor with the angular-dependent experimental data provides a reasonably definitive picture of the defect.

This section has emphasized the importance of the nuclear spin in detection of defects by magnetic resonance. However, too much of a good thing can create problems. In particular, difficulties arise when the crystal host is composed of atoms with 100% abundant nuclear spin. Depending on the strength of the inter-

action of the defect with host, the presence of many different sources of hyperfine interaction can lead to a series of barely resolved lines or even produce one broad EPR signal with all the powerful hyperfine information buried in its breadth. This is thought to be the cause of the limited information extracted from spectra in GaN because Ga has two isotopes, both with nuclear spin $\frac{3}{2}$, and nitrogen has one nearly 100% $I = 1$ isotope. The single broad line assigned to the Mg-related acceptor may be affected by unresolved hyperfine. The reader should be cautioned that the phrase *depending on the interaction with the host* is critical here. For instance the characteristic line pattern for Fe^{3+} and Mn^{2+} , transition metals that typically interact minimally with the host, are easily observed in GaN crystals [45.18, 19].

45.2.3 Interactions Involving More than One Electron

The above discussion suggests that theoretical calculations, which can predict the hyperfine interaction energy, can also be used to distinguish between the different charge states of a defect. However, in some cases, the charge state can be inferred from the experimental spectrum itself. This occurs if the number of electrons at a defect couple to a total spin greater than $\frac{1}{2}$. From the rules of adding spin angular momentum, it is known that n electrons can yield a total spin between 0 and $\frac{n}{2}$. In fact, Hund's rules tell us that the high spin is favored as the ground state; thus, all multiple electron defects should be paramagnetic. Of course Hund's rules do not strictly apply to a center surrounded by the many perturbing fields in a crystal lattice. Nevertheless, in some situations an EPR spectrum may best be described using a Hamiltonian of spin great than $\frac{1}{2}$. When this occurs, the term that must be included in the analysis is

$$H = \mathbf{S} \cdot \mathbf{D} \cdot \mathbf{S}, \quad (45.7)$$

where **D** is the fine-structure term, present only when $S > \frac{1}{2}$. Different physical situations can necessitate the use of this term including spin-orbit interaction and dipole-dipole coupling between different electrons. Here we will not be concerned with the origin of the term, but highlight two situations where the quadrupole term is used: an excited state of an $S = 0$ center and transition-metal impurities.

The EPR spectra discussed thus far represent the ground state of a defect. With the addition of optical illumination, one can populate the higher energy levels. This is particularly useful when the ground state of the center is an $S = 0$ EPR inactive state. Often, detection

Fig. 45.10 EPR spectrum of P6 and P7 centers obtained from neutron-irradiated 6H-SiC with the magnetic field oriented parallel to the c -axis. The sharp lines in the center are due to nitrogen and an unidentified defect (after [45.20], © APS 2001)

of an excited state may be verified by the fact that, after removal of the light source, the spectrum immediately returns to its pre-illumination condition due to the inherently short lifetime of the excited state. The P6 and P7 centers in n-type 6H-SiC irradiated with neutrons provide an example [45.20]. Figure 45.10 shows the EPR spectrum obtained from neutron-irradiated 6H-SiC during illumination with white light from a halogen lamp. The two sets of paired lines highlighted by brackets represent two similar defects (P6 and P7) on the three different symmetry sites of 6H-SiC (a , b , c). Pertinent to this discussion is that each line of the pairs reflects EPR transitions between spin states $m_s = -1$ to $m_s = 0$ and $m_s = 0$ to $m_s = 1$ of the $S = 1$ center. These lines are often referred to as fine structure. P6 and P7 are thought to represent different orientations of the same defect, although the exact model for the defects remains under debate [45.20, 21]. Note that recent data indicate that the centers are observed in heavily N-doped material without illumination, implying that $S = 1$ is the ground state. Whatever the case, the presence of the paired lines identifies the center as $S = 1$.

The transition element vanadium provides an example of how both the type of impurity and its charge state are determined directly from observation of the spectrum. Figure 45.11 shows two spectra obtained from 4H-SiC: a multiplet of nearly equal intensity lines adjacent to a second set of lines with much lower intensity

Fig. 45.11a,b EPR spectra of vanadium in 4H-SiC: (a) V^{4+} measured at 4 K with the magnetic field 10° from c -axis; (b) V^{3+} measured at 30 K with the magnetic field perpendicular to the c -axis

(Fig. 45.11a) and a pair of octets (Fig. 45.11b). According to the theory presented in the last section, the set of eight equally spaced lines in Fig. 45.11b indicates a 100% abundant $I = \frac{7}{2}$ nucleus. Checking the tables and considering typical unintentional impurities in SiC, it is concluded that the spectrum (Fig. 45.11b) arises from a vanadium atom on the cubic site [45.22]. A similar pair of octets, reflecting the hexagonal site, is found beyond the magnetic field range shown. Unfortunately, the spectrum in Fig. 45.11a is more complicated; suffice it to say that studies have shown that this spectrum also arises from a vanadium impurity, where the multiplet with high intensity arises from the cubic site and the set of low-intensity lines originate from the hexagonal site [45.23]. The presence of a single set of lines for each symmetry site in spectrum Fig. 45.11a and double set in Fig. 45.11b suggests that the former is an $S = \frac{1}{2}$ center while the latter is $S = 1$. V^{4+} in SiC has one unpaired electron, which would produce spin $\frac{1}{2}$, and V^{3+} has two, which could couple to spin 1. Thus, by simply examining the EPR line pattern, the impurity and its charge states are immediately determined.

How a high-spin defect produces a set of EPR lines at different magnetic fields is not immediately obvious from anything discussed thus far. Simply redrawing the $s = \frac{1}{2}$ energy diagram of Fig. 45.1 for $s = 1$ produces the levels shown in Fig. 45.12a, where the horizontal axis now represents a varying magnetic field and the verti-

Fig. 45.12a,b Energy levels of a spin-1 electron system in a varying magnetic field: **(a)** in the absence of any zero-field splitting; **(b)** in the presence of a perturbing field causing a splitting of the spin states in zero magnetic field. The vertical arrows represent the fixed quanta of microwave energy available for the transitions

cal axis is energy. The equal sized arrows represent the fixed quantum of microwave energy available for the transitions. It is apparent that the transitions between the different m_s states occur at the same magnetic field. What then, produces the separated pattern of lines observed for high-spin defects? Basically, any perturbing field that removes the degeneracy of the $m_s = \pm 1$ and $m_s = 0$ states at zero magnetic field will yield noncoincident resonance absorptions. Figure 45.12b illustrates the resulting energy levels where the separation D on

Fig. 45.13a,b EPR spectrum of Fe^{3+} in SrTiO_3 obtained at room temperature. The arrows point to the spin transitions that arise from Fe^{3+} ; the remaining EPR line is due to Cr^{3+} . Data were obtained with the magnetic field **(a)** at 0° and **(b)** at 30° with respect to the (100) direction

the vertical axis is referred to generally as the zero-field splitting. Once the states are separated at zero magnetic field, the $m_s = -1$ to $m_s = 0$ and $m_s = 0$ to $m_s = 1$ transitions no longer occur at the same magnetic field; thus, separate EPR lines will appear at each transition. In general $2S$ EPR resonances will occur. While several types of interactions can separate the energy of the degenerate spin states, the most common is the anisotropic magnetic dipole-dipole interaction. The calculation required to demonstrate the effect of the zero-field splitting is straightforward and is shown in many texts [45.1, 8].

The fine-structure lines produced by high-spin centers have different characteristics than those of hyperfine lines discussed at the end of the previous section. For example, the intensity of each EPR line is not the same. For any $S > 1$ center, the intensities of resonance lines from the various m_s transitions exhibit different, but predictable, variations. Figure 45.13a shows this for Fe^{3+} in SrTiO_3 measured with the magnetic field oriented along the c -axis of the sample. The five lines highlighted arise from the five transitions of the $S = \frac{5}{2}$ center. The remaining line represents Cr^{3+} . The relative integrated intensities of the Fe^{3+} lines, 5 : 8 : 9 : 8 : 5, follow from the transition-matrix element between the $\frac{5}{2}$ to $\frac{3}{2}$, $\frac{3}{2}$ to $\frac{1}{2}$, $\frac{1}{2}$ to $-\frac{1}{2}$, $-\frac{1}{2}$ to $-\frac{3}{2}$, and $-\frac{3}{2}$ to $-\frac{5}{2}$ spin states

$$g\mu_B B_x \left\langle \frac{5}{2}, m_s^i \left| S_x \right| \frac{5}{2}, m_s^f \right\rangle, \quad (45.8)$$

where B_x is the microwave magnetic field perpendicular to the applied field, m_s^i and m_s^f represents the magnetic spin quantum number for the initial and final states,

Fig. 45.14 EPR spectrum of Fe^{3+} in a GaN crystal obtained at 4 K

respectively, and S_x is the spin angular momentum operator that ultimately raises the electron from the lower state to the upper state. See [45.1, appendix C] for details. This intensity pattern would apply to any $S = \frac{5}{2}$ center with the simple $|s, m_s\rangle$ wavefunctions. Similar patterns may be predicted for other $S > \frac{1}{2}$ centers. For example, Fig. 45.14 shows that the line pattern for the $S = \frac{5}{2}$ impurity Fe^{3+} in GaN also consists of five lines of unequal intensity. The sharpness of the lines in GaN compared with those in SrTiO_3 most likely reflects a lower density of extended defects or less strain. The line width also explains why the relative amplitudes are different in the two samples; however, it is not obvious why certain transitions should be broadened more than others.

Not all situations involving high-spin defects are as straightforward as the two mentioned here. Sometimes the crystal field, the electric field generated by the ions or ligands surrounding the defect, dominant spin–spin and spin–orbit interactions ultimately producing wavefunctions which are linear combination of the simple spin states, $|s, m_s\rangle$. Crystal-field effects are exhaustively discussed in many texts [45.24]. For EPR, the only point is that the ground-state orbital wavefunction is determined by the field strength, thereby establishing the type of spin wavefunction appropriate for a particular defect. When the crystal field is much greater than other interactions, an EPR spectrum greatly different

Fig. 45.15 EPR spectrum of Fe^{3+} in a LiNbO_3 crystal obtained perpendicular to the c -axis at room temperature

from the two iron spectra in Figs. 45.13 and 45.14 is produced. Figure 45.15, showing Fe^{3+} in LiNbO_3 , illustrates the point. Here, the trigonal crystal-field effect is of the same order of magnitude as the Zeeman effect, yielding an EPR signal significantly different from the five-line pattern seen previously. Additional interaction terms must be added to the Hamiltonian in order to unravel the meaning of the spectrum [45.25, 26].

Like the Zeeman and hyperfine terms, the fine-structure term can produce angular dependence. In some cases, a simple shifting of lines occurs as seen in Fig. 45.13b. However, often spectra dominated by D exhibit angular-dependent intensities. This occurs when the appropriate wavefunctions are linear combinations of the $|s, m_s\rangle$ states. Because the crystal field is directional, different wavefunctions are produced at different orientations of the sample with respect to the applied B field. The angular-dependent wavefunctions then lead to angular-dependent transition-matrix elements (45.8) and, therefore, varying spectral intensities. Note that high magnetic fields and high frequencies may be employed to avoid complications due to the large crystal field. However, using microwave frequencies larger than 10 GHz is tedious, involving different types of waveguides, cavities, and microwave bridges than those used for the lower frequencies. Often, it is easier to deconvolve the complicated experimental data using straightforward calculations than to execute an EPR measurement at sufficiently high frequency as to avoid the crystal-field effects.

To summarize, we have considered three energy contributions to a point defect in the presence of an applied magnetic field: the electronic Zeeman term (45.2), the nuclear hyperfine interaction (45.6), and the fine-structure term (45.7). In general, all three effects may be present, so that the appropriate Hamiltonian to begin analysis of a spectrum is

$$H = \mu_B S \cdot g \cdot B + \sum_j S \cdot A \cdot I + S \cdot D \cdot S. \quad (45.9)$$

For defects with $S > 1$, additional terms may be added depending on the nature of the defect and its surroundings. Because many of the defects typically encountered involve only two or more of the terms above, no discussion of the additional terms is presented here. Equation (45.9) is not the most *user-friendly* equation ever presented to the average reader. For those with peripheral interest in EPR, understanding how the number and separation of EPR lines are used to determine defect structure should be sufficient to appreciate the power of the technique. More interested readers will find the quantum-mechanical calculation techniques required for complete analysis in the many references referred to throughout this section, specifically [45.1, 8].

45.2.4 Total Number of Spins

In addition to a physical description, EPR data may provide the total number of centers of a specific defect. This is accomplished by comparing the spectrum of an unknown quantity of a defect with that obtained from a known quantity. Significantly, the EPR signal from the standard need not arise from the same defect or even a different defect in the same material. This convenience is afforded by the fact that the spin-flip probability is usually independent of the local environment. Common calibration standards include 2,2-diphenyl-1-picrylhydrazyl (DPPH) and the phosphorus signal in powdered, heavily doped, n-type Si. In principle, the comparison can lead to an absolute number of spins with an accuracy of 50% with sensitivity as low as 10^{10} spins [45.1]. However, the reader should be warned that the sensitivity depends strongly on line width and number of lines. The number quoted is based on a single resonance with 1 G line width. For a signal of 10 G line width composed of five lines, the minimum detectable spins increases by a factor of at least 50. Other factors

such as temperature and microwave saturation also limit sensitivity. Such issues are discussed in [45.1, appendix E].

A few items to remember regarding the absolute spin measurement are:

1. Only the paramagnetic state of any defect is being measured. For instance, the number of acceptor impurities may be calculated. However, the result is limited to acceptors that have captured the hole in the valence band. For this reason, EPR of acceptors (and donors) is often performed at low temperature to more closely reflect the total number. Compensation may further reduce the number of EPR-active acceptor sites. The amount of the impurity calculated from the acceptor signal will not include aggregates, complexes or other forms of the impurity; however, different EPR signals may be related to these entities and measured separately.
2. Only the total number of centers is determined. Additional experiments are needed to find the spatial distribution of defects. When concentration is given in an EPR study, the centers are assumed to be uniformly distributed throughout the material unless otherwise stated.
3. Defects arising from complex wavefunctions, such as high-spin centers in a strong crystal field, will exhibit intensities that are dependent on orientation. In these cases, one must first determine the various transition rates before the number of defects may be calculated.

Traditionally, the absolute number of spins is not the focus of an EPR study. This is partially because of the many caveats discussed above, as well as the difficulty of generating an accurate standard. One powerful aspect of the spectroscopy that is commonly employed, however, is determination of the variation in number of defects by measuring the relative amplitude of EPR signals. For a single EPR resonance that does not change shape during the course of a study, the amplitudes of a signal may be used to indicate varying defect densities. This is the approach used in many of the experiments discussed below. For the types of centers mentioned in item 3, however, careful alignment of the samples is required between measurements so that the amplitude changes truly reflect the number of spins and not angular-dependent transition probabilities.

45.3 Scope of EPR Technique

Having presented the basis for interpreting EPR spectra, without question the most challenging feature of EPR for most readers, the remainder of the chapter focuses on the power of EPR in terms of the types of defects detectable and typical correlation studies. All of the examples in the section above are simple point defects, either an intrinsic defect or single-atom impurity. Many other forms of defects are detected including substitutional, interstitial, antisite, vacancies, vacancy pairs, antisite–vacancy pairs, and impurity–vacancy pairs. The only requirement is that the defect be paramagnetic in the as-grown material or be able to be made paramagnetic with an external perturbation.

EPR was first used on bulk crystals, and indeed this is where the full power of the technique is realized. However, with the ongoing push towards miniaturization and increasing desire for a *chip-based* world, films less than one micrometer thick and particles with less than 100 nm diameter are typically encountered. While this has been the case in electronics for more than a generation, miniaturization of optical and even microwave devices is increasingly popular. Indeed, one of the most recent initiatives involves growing films using crystals with well-known microwave or magnetic properties. Ultimately, these will be deposited onto a full wafers with future integration into Si electronics as the goal.

The utility of applying EPR to films is not obvious because, although the technique is sensitive to as few as 10^{11} centers, for traditional defect analysis these defects must be isolated. A simple calculation shows that a micrometer-thick film with 10^{11} centers uniformly distributed yields 10^{15} cm^{-3} defects. While this is not an unrealistic number for the types of films of interest today, the calculation represents the most hopeful situation: the minimum spin detection limit and the thickest films of interest. Nevertheless, the example does show that studying films is not out of the question. Indeed many successful experiments are reported in the literature. Most take the advantage of stacking many film–substrate samples so that the signal intensity may be maximized. Careful alignment is required in these cases so that the crystallinity of the samples is not compromised. The examples below illustrate several different types of film–substrate studies:

1. Intrinsic defect in the *bulk* of a micrometer-thick film
2. Defect at a crystalline substrate–amorphous film interface
3. Near-surface impurities on a polycrystalline film.

45.3.1 Defects in a Thin Film on a Substrate

The first situation addressed is the study of a simple point defect in a film, a donor in GaN. The only difference between the film and bulk experiments in this case is the preparatory steps for the measurement. Usually, several film–substrate samples are stacked together to increase the total amount of GaN being studied. Furthermore, GaN is typically grown on sapphire or SiC. In either case, the substrate must be carefully studied to distinguish the substrate EPR signals from those of the film. The microwave absorption utilized in EPR detection completely penetrates most semiconductors and insulators, so that the technique senses the substrate and film equally. Luckily, the well-known EPR signatures of defects in sapphire are highly anisotropic, so that their contribution to the spectrum may often be minimized by prudent orientation of the sample with respect to the magnetic field. The only defect to be avoided in n-type SiC substrates is the nitrogen donor, which is easily resolved from the donor in GaN.

Most of the information about the donor EPR signal in GaN is contained within a work by Carlos and coworkers [45.27]. No hyperfine could be detected in the spectrum, leaving the chemical origin of the center uncertain, but several EPR characteristics suggest that the resonance represents an electron in a donor band. Work in our laboratory shows that the spectrum is found only in n-type samples, and that the signal intensity increases with increasing donor density for $n = 1 \times 10^{14} - 1 \times 10^{17} \text{ cm}^{-3}$ [45.28]. Carlos and coworkers concentrated on the spectroscopic characteristics of the EPR signal to demonstrate the donor assignment. Their measurements suggest that the *g*-value is typical of a donor electron and the angular dependence reflects that of the hexagonal lattice. Furthermore, the line width indicates that the paramagnetic electron is not *attached* to the donor atom, and the temperature dependence of the line width, shown in Fig. 45.16, eliminates a conduction-band electron. The different symbols represent data obtained from various thickness samples as indicated on the figure. The main point here is that all sets of data exhibit a decreasing line width until 20 K, followed by an increasing line width. The former region is

Fig. 45.16 Line width of the donor signal in GaN measured at selected temperatures. The smooth brown line is a $T^{5/2}$ fit to all of the data; other lines merely connect data points (after [45.27], © APS 1993)

thought to be due to motional effects and the latter due to coupling to acoustic phonons, neither of which should occur if conduction-band electrons were involved.

Although there are several other EPR studies of point defects in crystalline thin films, the small signal size inherent to the low sample volume limits the number of intensive investigations. Homoepitaxial films are highly unlikely to produce meaningful results about the film because the layer of interest cannot be separated spectroscopically from the bulk substrate. Consequently, many film studies were performed on amorphous material, the most common of which was SiO₂ films on Si substrates. Although many studies focused on oxide films irradiated by γ -rays or higher energy, several studies addressed the intrinsic defects in the oxide films [45.29–35]. In some cases, the defects, specifically an oxygen vacancy known as an E' center, was successfully correlated with many of the electrical trapping effects in metal–oxide–semiconductor field-effect transistor (MOSFET) devices [45.34, 35]. Other studies of film–substrate systems in which the point defect resides in the *bulk* of the film include diamond and MgO [45.36–38].

45.3.2 Defects at an Interface

The second type of center addressed in this section is one located at an interface, specifically the Si–SiO₂ interface. In Si devices, paramagnetic defects at the Si–oxide interface are known to be directly related to electrically active trapping sites that alter device performance [45.39, 40]. For this reason, much EPR work has concentrated on a dangling bond defect located at the semiconductor–oxide interface [45.39–44]. Several different types are found in pure silicon-based interfaces, each involving an unpaired electron on a Si atom located on the semiconductor side of the interface [45.40, 42]. Centers with a Ge dangling bond and C dangling bond are seen in SiGe–oxide and SiC–oxide interfaces, respectively [45.41, 43, 44]. The dangling-bond-like defects are referred to collectively as P_b centers.

In general, EPR cannot selectively detect centers at surfaces and interfaces because the microwave radiation penetrates the entire semiconductor substrate. However, for a perfectly flat surface, the angular dependence of the EPR resonance may provide enough information to deduce the surface nature of the center, as was done for the Si P_b center located at the interface between a (111) Si substrate and amorphous SiO₂ layer [45.42]. To understand the difference between interfacial and bulk angular dependence one must reconsider the discussion of the *g*-tensor presented earlier. *g* is a tensor because the absorbed energy depends on the orientation of the applied magnetic field and a preferred direction of the dipole moment. However, in a crystal a specific defect may be located at one of several different symmetry-related sites. For example, the simple dangling bond in bulk Si may be directed in any one of four (111) bonding directions, all of which may make a different angle with respect to the applied field depending on the orientation of the sample (Fig. 45.17). Since the defect may be any of the four (111) bonding directions of tetrahedral Si, the EPR spectrum should reveal four lines when the magnetic field is oriented at a general angle with respect to the surface normal of the sample. For special orientations, such as *B* rotated in a (111) plane,

Fig. 45.17 Schematic model of a tetrahedrally coordinated atom (small circle) with the magnetic field directed at an arbitrary angle with respect to any one of the [111] directed bonds. The dangling bond could be any one of the four bonds with the large circle removed

Fig. 45.18 Schematic model of a tetrahedrally coordinated atom at an interface, where one of the $[111]$ -directed bonds points perpendicular to the interfacial plane. The vertical solid line marks the ideal interface plane between the bulk and the substrate

the bond perpendicular to the plane should produce one isotropic line and the remaining three dangling bonds would generate one anisotropic line three times larger than the isotropic one.

Now perhaps the reader can see how an interface defect would be different. At an interface (or surface) not all of the four directions would be identical. The easiest case to imagine is the (111) surface, where one of the four bonds is perpendicular to the plane of the interface along a now unique (111) direction (Fig. 45.18). The other three possible bonds would be pointing into the *bulk* of the Si substrate, and if paramagnetic, would produce a different g -tensor than the interfacial defect. Since silicon is a perfected material, generally the back bonds are unbroken and do not contribute an EPR signal. Therefore, if the magnetic field were in the plane of the interface and perpendicular to the dangling bond, one would expect to see only a single isotropic EPR line due to the dangling bond at the interface. Unfortunately rotation in the plane of the interface is not realistic, but Poindexter and coworkers performed measurements with B in the $(11\bar{2})$ and $(1\bar{1}0)$ planes, revealing the expected angular dependence. Figure 45.19 shows the g -value versus angle with respect to the (100) direction for a P_b center in thermally oxidized (111) Si. The appearance of only a single g -value at each angle indicates that only one EPR line is observed at each angle. The coincidence of the unfilled and filled circles, which represent data obtained from two different planes of rotation, imply that the angular dependence of the spectrum is identical for the two different planes. Both observations are expected for a dangling bond between the (111) surface of Si and the overlying oxide film.

The relationship of the P_b center to Si was confirmed by observation of the nuclear hyperfine interaction. Detecting the hyperfine in this case is a heroic

Fig. 45.19 g -values of the P_b center measured in oxidized Si with the magnetic field in the plane (a) (small circles) and plane (b) (large circles) (after [45.42], © AIP 1979)

experiment considering the low atomic abundance of ^{29}Si and small total number of defects at an interface. Nevertheless, Brower stacked 35 oxidized Si wafers together to observe the hyperfine lines, confirming that the nucleus associated with the dangling bond is Si [45.45]

As one might expect, other types of interfaces may be studied with EPR. However, to the author's knowledge, the only reports in the literature focus on the semiconductor–oxide system, specifically SiC–SiO₂ and SiGe–SiO₂ [45.41–44]. In both cases oxidized porous material or oxygen-implanted substrates were used, and the interfacial nature was confirmed through etching studies. The planar interfaces necessary for the angular-dependent studies are not achievable at this time for these types of materials. In principle, many other types of interfaces could be examined. The limitation, however, is always preparing the samples in such a way as to maximize the amount of interface in the EPR cavity. Multilayer heterostructures should make ideal samples for study, but the author is not aware of any attempts to date.

45.3.3 Defects at Surfaces

A surface may be thought of as a special case of an interface, one in which one side of the interface is the ambient atmosphere. In principle, the Si P_b center should be observable on bare Si. And indeed, one *should* be able to detect the center if one could do an EPR measurement in vacuum. Si oxidizes readily in air at room temperature, thus an unoxidized surface is virtually unobtainable under the conditions required for an EPR study. Nevertheless, many surface defects are

reported in the literature, but most relate to the roughened surface caused by cutting or polishing [45.46]. Such centers exhibit an isotropic g -value and are often passivated in the presence of hydrogen [45.47].

For single crystals, one may differentiate between bulk and surface defects in much the same way as was discussed for bulk and interface. However, for polycrystalline materials the situation is somewhat different, as is illustrated in the following example. Cr-doped polycrystalline SrTiO_3 films, 1700 nm and 350 nm thick, were grown on sapphire substrates [45.48]. The powder-pattern spectrum typical of a polycrystalline material was resolved into two separate spectra: one with a g -value of 1.977, typical of Cr^{3+} in SrTiO_3 , and a second center with $g = 1.974$. The authors show that the latter is consistent with a Cr^{3+} impurity located near the surface. As discussed earlier, the symmetry of a surface defect is inevitably lower than that of a bulk defect and angular-dependent measurements may be used to exploit the difference. However, the random nature of the polycrystallites requires a different data analysis than that of a pure crystal. Calculations by *Deigen* and *Glinchuck* show that the g -value for a surface defect should be shifted from that found in the bulk by an amount proportional to the angle between the applied field and the surface normal [45.49]. In the Cr-doped films, the EPR signal represented by $g = 1.974$ shifts as the sample is rotated in the magnetic field. The angular dependence of this portion of the signal agrees with the theory predicted for a surface center. Also, the authors point out that the ratio of the 1.974 signal intensity to that for the 1.977 signal is larger in the 350 nm films than in the 1700 nm ones, as expected for a surface center in a thinner sample.

The trapping of impurities within the bulk of sub- μm -sized particle is a well-known difficulty, and several studies have employed EPR to distinguish bulk and surface impurities in these nanoparticles. The Mn^{2+} impurity in ZnS provides just one example [45.50]. EPR of nanoparticles have also been used to address the relationship between the defects and ferromagnetic or ferroelectric behavior [45.51]. Si surface centers, not surprisingly, are often addressed in EPR studies of Si nanodimensional materials [45.52, 53].

45.3.4 Nondilute Systems

This chapter, as well as much of the EPR literature, focuses on low concentrations of isolated point defects separated by at least several atomic units. The interpretation of spectra requires a significantly dif-

ferent approach when the defect-defect distance gets smaller. More specifically, new terms such as the exchange interaction enter the Hamiltonian if nearby spins on separate defects begin to interact. *Ferher* et al. demonstrated this for P-doped Si [45.54] using samples with two different donor concentrations, 1×10^{17} and $4 \times 10^{17} \text{ cm}^{-3}$. The spectra reveal several pairs of EPR lines between the hyperfine lines from the isolated phosphorus atoms. *Ferher* demonstrated that the number of pairs increased as the concentration of phosphorus increased, suggesting that at sufficiently high density the spacing between some of the dopants is suitable for electron-electron exchange. The work was extended by *Maekawa* and *Kinoshita* studying Si doped with 10^{16} – 10^{19} cm^{-3} phosphorus atoms [45.55]. Temperature-dependent measurements confirmed the role of the exchange interaction suggested by *Ferher* for the most lightly doped samples and revealed the presence of electron-hopping and impurity-band conduction at the highest temperatures.

Bencini and *Gatteschi* discuss the role of the exchange interaction in EPR spectra for a variety of different circumstances ranging from transition-metal dopants to protein-based systems [45.56]. All cases including exchange and superexchange are discussed. The emphasis of these types of studies is distinctively different from that discussed above for the nondilute systems. For example, spin-spin correlation as well as spin-spin and spin-lattice relaxation times, are emphasized. Nuclear hyperfine may often be lost in the typically large line widths of exchange-dominated systems. Thus, the interaction of the defects with the local environment are the focus of the study, rather than the detailed atomic structure of a specific defect. Finally, the case of a nondilute system of a ferromagnetic material should be pointed out, in which the collection of spins creates a magnetic field without the application of an applied field. The magnetic resonance of such a system, referred to as ferromagnetic resonance, requires entirely different analysis from the paramagnetic resonance discussed in this chapter. The reader should consult [45.57, 58] for information on ferromagnetic resonance.

Much of the literature of nondilute systems is concerned with one- and two-dimensional systems of spins, reminiscent of dangling bonds at an extended defect. Unfortunately, sensitivity may present a limitation. In the case of strongly coupled spins, the minimum detectable number of spins would be severely crippled by the line width typical of dilute systems. Specifics are difficult to estimate, but most nondilute systems produce line widths hundreds of G wide, thereby de-

creasing EPR sensitivity from the typical 10^{11} spins to 10^{14} spins. Consider a material with 10^8 cm^{-2} line defects each $1 \mu\text{m}$ long, consisting of 1×10^3 defects. This yields 1×10^{11} defects in each cm^2 of material,

an amount on the edge of detectability for even a 1 G line width. However, in emerging materials where the concentration of extended defects may greatly exceed 10^8 cm^{-2} , EPR detection may not be unrealistic.

45.4 Supplementary Instrumentation and Supportive Techniques

As with any technique, correlation studies using data obtained from other techniques or the incorporation of additional instrumentation enhances the amount of information gained from the study. Many different types of techniques and layers of instrumentation have expanded the capabilities of EPR over the years. First, one example using additional instrumentation will be presented: photo-EPR. Then several correlation studies will be discussed, including electrical measurements and thermal annealing. Additional examples involving expanded instrumentation are briefly reviewed in the final section of the chapter.

In this section the term *defect level* is used extensively, so the reader must fully understand what it means. A defect level is similar to an ionization energy in that it represents the difference in energy between two charge states. In the case of ionization, however, the final state is represented by an electron infinitely far away from the ion. For a defect in a crystal, the electron is located in the conduction band after removal from the defect. The defect level is the energy necessary to remove an electron from a defect and place it in the conduction band. Similarly, a defect level may be viewed as the energy required to excite an electron from the valence band to the defect. The level is represented schematically as shown in Fig. 45.20. The lines labeled E_v and E_c are the valence- and conduction-band edges, respectively. The line labeled $X^{-/0}$ is the defect level, representing the energy required to change the charge

state of defect X from negative to neutral. The inverse, the energy required to change defect X from neutral to negative, is the same level. Since a defect level is always quoted with respect to a band edge, it is typically written as $E_c - E_x$ or $E_v + E_x$. From the discussion, it should be clear that a defect level has meaning only with respect to specific charge states. That is, the statement *the defect level of boron in SiC* is ambiguous. One should say *the defect level of boron from the neutral to negative charge state*, or $B^{-/0}$. However, for typical acceptor and donor impurities the charge states are well known and often omitted. For less common impurities the complete statement is imperative to avoid confusion.

Several different descriptive terms are used in conjunction with a defect level. *Shallow* and *deep* are used to distinguish the energy difference between the level and a band. The former generally refers a defect level that may be depopulated at room temperature; the latter implies any level sufficiently far from a band such that it is stable at room temperature. Recently a third descriptor, *mid-gap level*, has been introduced. This term applies to a level that is close to the center of the bandgap of a wide-bandgap semiconductor. Operationally, it generally refers to a level more than about 1 eV from either band edge, and one that is not easily detected by conventional thermal techniques such as deep-level transient spectroscopy.

Some defects have more than one level in the bandgap. The term *amphoteric* is used if the levels are $X^{0/+}$ and $X^{-/0}$, where the former is referred to as a donor level and the latter as an acceptor level. Confusion arises when one talks about transition-metal defects because the original work was performed on ionic insulators rather than semiconductors. Thus, the ionic notation is used. For example, for vanadium with five outer electrons in tetrahedrally bonded SiC, the neutral state is referred to as V^{4+} because four of the five outer electrons are transferred to the four *positive* C atoms surrounding the site. The $V^{4+/5+}$ level is referred to as the donor level because the vanadium becomes neutral (V^{4+}) after releasing an electron to the conduction band. Similar V^{3+} is negative and $V^{3+/4+}$ is the acceptor level.

Fig. 45.20 Schematic energy diagram illustrating the concept of a defect level $X^{-/0}$ (see text)

Another confusion that may arise is the difference between a defect level measured using a standard thermal technique such as deep-level transient spectroscopy (DLTS) and an optical method, such as optical absorption. The former detects transitions between ground states, whereas in the latter measurement the final state may be an excited state of the optically induced charge state. In other words, using thermal methods one senses only zero-phonon transitions, whereas optical excitation induces the Franck–Condon (vertical) transition. By definition, a defect level is a thermally determined entity. The energy difference between the zero-phonon and Franck–Condon levels may be interpreted in terms of a structural relaxation of the defect, as is discussed by Godlewski et al. [45.59–61].

45.4.1 Photo-EPR

As mentioned earlier, optical illumination may excite the EPR active state of a defect in two different ways. Diamagnetic ($S = 0$) centers may be excited to their triplet ($S = 1$) state where the $\Delta m_s = 1$ transitions within the $S = 1$ manifold may be seen. An example involving the P6/P7 centers was presented. In this section, photo-EPR involving a change in charge state is discussed. Radiation such as near-infrared, visible or ultraviolet may ionize a defect by removing an electron to the conduction band or by exciting an electron from the valence band. This not only enables detection of previously nonparamagnetic centers, but may lead to determination of the electrical level of the defect [45.59–61]. For instance, the transition of vanadium from the $4+$ to $5+$ charge state $V^{4+/5+}$ was found to be 1.6 eV above the valence-band edge E_v using photo-EPR [45.22]. Several groups have presented studies for the defect level of the carbon vacancy V_c [45.62–64], and Son and coworkers used photo-EPR to address the levels of several different defects in SiC [45.65].

The technique consists of measuring the resonance signal during illumination with sub-bandgap light, usually from a 100 W-lamp monochromator system. Two different approaches may be used: steady-state and time-dependent photo-EPR. Almost all of the studies involve the former because the latter involves extensive time and is feasible only for defects with sufficiently long relaxation times. The typical time for an EPR scan, tens of seconds, limits the temporal resolution and the type of defects studied. Nevertheless, Godlewski and coworkers applied time-dependent EPR to impurities in ZnS and GaAs [45.59, 60]. Experimentally, the intensity of an EPR signal is monitored as a function of time

while illuminating the sample with a fixed photon energy, and the time dependence is fitted to one of many equations depending on the types of transitions involved. Cases involving interaction between acceptors, donors, and conduction/valence bands are thoroughly covered in a review article by Godlewski [45.61].

To understand the analysis, consider the simplest case of a single transition involving defect ionization of an electron to the conduction band. The time dependence of the signal intensity recorded at a specific wavelength should follow a first-order kinetic process

$$\Delta n(t) \propto 1 - \exp\left(\frac{-t}{\tau}\right), \quad (45.10)$$

where Δn represents the normalized change in defect concentration during illumination and τ is the time constant for the process. If the incident light intensity I can be measured, the cross section σ can be calculated from $\frac{1}{\tau} = I\sigma$. The intensity of light inside the sample may be estimated if all of the optical properties of the material are known. Typically samples are transparent to the illumination wavelengths used in photo-EPR, so the incident intensity serves as a good approximation to the intensity of light at the defect. Ideally, a plot of the cross section versus excitation wavelength produces a curve with a threshold reflecting the defect level of the center. Figure 45.21 illustrate some of these ideas, where the time evolution of the V_c^+ signal in 4H-SiC is shown for excitation energies of 1.73 eV (Fig. 45.21a) and 2.3 eV (Fig. 45.21b). The data represent two processes: one for ionization of an electron from V_c^0 to the conduction band (Fig. 45.21b) and the second for excitation of an electron from the valence band to V_c^+ (Fig. 45.21a). The good fit to a single exponential (solid line) supports a model based on a simple transition involving only one defect. When measurements are made with sufficiently low light intensity such that the number of V_c^+ defects generated by the light is proportional to I , the cross sections are shown to be on the order of 10^{-15} and 10^{-16} cm² for ionization to the conduction band and excitation from the valence band, respectively [45.64]. Unfortunately, the very long time constants typical of these samples precluded a detailed study of the energy dependence of the cross section. However, the two energies measured at the shortest time constants, 2.3 eV and 1.78 eV, may be used as estimates for the transitions energy from the defect to E_c and from E_v to the defect. The fact that they sum to a quantity larger than the bandgap of 4H-SiC (3.26 eV) suggests that some of the energy is consumed by relaxation of the defect upon capture or release of an electron. The value for

Fig. 45.21a,b Time-dependent photo-EPR data of V_c^+ measured in high-purity semi-insulating 4H-SiC. The photon energy used was (a) 1.78 and (b) 2.3 eV. The solid lines are exponential fits to the data

the relaxation energy extracted from the data, 0.8 eV, is consistent with that predicted by theory, supporting the simple interpretation of the results [45.66]. Analysis of steady-state photo-EPR data yields a similar result for the relaxation energy [45.66].

A more thorough application of time-dependent photo-EPR is presented by Godlewski [45.61]. Here, defect relaxation as well as phonon coupling and a model of the purely electronic cross section are included in the energy dependence of the photo-EPR optical cross section used to fit the data. Thermalization measurements are included along with the optically induced spectra to study the influence of defects with levels located very close to a band edge. The defect levels and relaxation energy are determined for $Cr^{+}/^{++}$ in ZnS and GaAs. These values, which compare favorably with those obtained from optical absorption studies, provide validity to the photo-EPR approach.

Although powerful, time-dependent photo-EPR requires that the transition times be long enough to be detected by the relatively slow EPR measurements and short enough to be measured within the lifetime of an experimentalist. The steady-state photo-EPR method provides a simpler approach to determining defect levels; however, the technique cannot distinguish the influence of multiple transitions and is therefore limited to pure materials in which a single dominant defect prevails. The term *steady state* photo-EPR refers to measuring the EPR signal after

a fixed period of illumination at a selected wavelength. Results obtained on high-purity SiC are shown in Fig. 45.22, for V_c^+ (brown circles), nitrogen (triangles), and boron (gray circles). In general, the threshold at 1.5 eV in the V_c^+ data is interpreted as the transition of the electron from E_v to the defect and the one at 1.7 eV is thought to represent the transition from the defect to the conduction band. The thresh-

Fig. 45.22 Steady-state photo-EPR data obtained from high-purity semi-insulating 4H-SiC. The left vertical axis reflects the relative concentration of V_c^+ (brown circles); the right, boron (gray circles) or nitrogen (triangles)

olds are equivalent to transition energies obtained using thermal excitation in that they typically represent zero-phonon transitions. As such, the difference between each threshold value and the energy obtained from the time-dependent data of Fig. 45.21 is the difference between the Franck–Condon and zero-phonon transitions. In other words, the difference is a measure of the relaxation energy. However, as Fig. 45.22 shows, several other photoactive centers are detected, complicating this interpretation. Thus, while interpretation of the data shown in Fig. 45.22 provides a working model, many additional studies including comparison with other techniques need to be performed to completely understand the transitions.

45.4.2 Correlation with Electrically Detected Trapping Centers and Defect Levels

The importance of crystalline semiconductors to the electronics industry has spurred an overwhelming number of studies correlating charge-trapping centers and defect levels to impurities and intrinsic defects. For example, instabilities in metal–oxide–semiconductor field-effect transistors (MOSFETs) initiated numerous experimental programs linking charge-trapping centers in the thermally grown gate oxides with well-known EPR defects in quartz and glass [45.5, 6]. In crystalline materials, the electrical levels in semiconductors detected by deep-level transient spectroscopy (DLTS) and temperature-dependent Hall measurements (TDH) have been attributed to EPR-detected defects with similar thermal properties [45.68, 69]. Also, the interface defects discussed above were widely studied in terms of their electrically detected counterparts. Below, a few studies that employ electrical–EPR correlation measurements are summarized.

Before reading the examples, one must appreciate the limitations of comparisons between EPR and most electrical techniques. The same sample is seldom used for both measurements because the area required for an electrical method such as capacitance–voltage (C–V) or DLTS is often an order of magnitude less than that required for EPR. Besides, a metal contact is often necessary for electrical measurement, while a thick flat metal surface suitable for good electrical contact severely cripples the sensitivity of EPR. Several variations have been devised to avoid these difficulties, the most successful of which is described below, but in most cases separate pieces are used for the two different types of measurements.

Acceptor Activation and Passivation

In the bulk of semiconductors, many of the correlation studies focus on the identification of acceptors or donors and the mechanism by which they are passivated by hydrogen. The dominant GaN acceptor, magnesium, provides one example. Using samples with magnesium concentration in the range 10^{18} – 10^{19} cm^{−3} Glaser and coworkers studied a broad, axially symmetric signal found only in Mg-doped GaN. Additional work by others showed that the passivation of holes and the EPR defect followed the same trends [45.70, 71]. Activation by heat treatments in an inert environment produced similar results for the EPR signal and holes also [45.72]. Figure 45.23 shows a comparison of the resistivity measured by Nakamura and coworkers (gray squares) and the intensity of the Mg-related EPR signal (brown circles) observed in our laboratory during consecutive annealing treatments in dry N₂ [45.67]. In this comparison, not only are the samples different physical pieces, but they were grown by different groups using somewhat different methods. Nakamura's samples were grown by a metalorganic chemical vapor deposition (MOCVD) technique at 1035 °C on a GaN buffer layer using a sapphire substrate, while our samples were grown by organometallic CVD on an AlN buffer layer using an n-type 4H-SiC substrate. Nevertheless, the comparison is revealing: the resistivity decreases as the EPR signal intensity increases. This behavior is consistent with the release of hydrogen from an acceptor.

Fig. 45.23 Relative amount of Mg-related acceptors in GaN (brown circles) and resistivity (gray squares) after sequential annealing treatments in N₂ (after [45.67]). © Phys. Soc. Japan 1992)

Similar studies of samples grown by molecular-beam epitaxy and heat treatments in hydrogen are all consistent with the interpretation of acceptor activation by release of hydrogen [45.71]. Although the need to activate the CVD-grown GaN acceptor with a post-growth N_2 anneal was well accepted by the time of the EPR/annealing study, the spectroscopy confirms that the entity directly involved in the activation process is the acceptor. Observation of the behavior in only Mg-doped GaN suggests the relationship with magnesium, and infrared (IR) studies have indicated that the acceptor is a Mg–N complex, consistent with the broad EPR signal [45.71, 73, 74]. Other studies of acceptor and donor passivation are described by Gendron and coworkers, and separately Gerardi et al., studying N-doped (n-type) and Al-doped (p-type) SiC [45.75, 76].

Deep Levels: DLTS

Naturally, there is a desire to know the physical entity responsible for the deep levels in semiconductors. In the early days of Si, DLTS and EPR were often performed in the same laboratory in an effort to understand the nature of the deep levels. The C_iC_s (interstitial C–substitutional C pair) in Si provides one of the most complete examples linking a deep level to an EPR center [45.77, 78]. In this case the metastable properties of the center were monitored by several techniques, EPR, DLTS, photoluminescence, and optically detected magnetic resonance, allowing for strong correlations to be developed. The details are found in [45.78]. More recently, the concentration of the Z1/Z2 DLTS signal in 4H-SiC was shown to correlate with an EPR signal known as SI-5, a high-spin center thought to be a divacancy or V_c-C_{si} pair [45.68]. Figure 45.24 illustrates the comparison between the concentration of the SI-5 EPR signal and Z1/Z2. In addition to the one-to-one correspondence in the number of centers, it was pointed out that illumination was required to observe SI-5, consistent with the negative U character attributed to the DLTS signal. Once the model for SI-5 is confirmed, the DLTS/EPR study will provide a rare assignment of a physical entity in SiC to a deep level detected by DLTS.

Compensating Defects

The importance of semi-insulating semiconductor materials to the formation of high-power electronics has spurred investigations into the deep level, or more appropriately mid-gap level, responsible for compensation. The levels are detected with several techniques including optical DLTS, temperature-dependent Hall

measurements, and photo-EPR. A comparison of the latter two techniques has led to the assignment of vanadium and several different intrinsic defects as compensating centers in SiC [45.69]. However, the conclusions should be accepted with a great deal of caution. First, electrical measurements of these high-resistivity materials are crippled by the difficulty of making ohmic contacts. Also, temperature-dependent Hall measurements are often limited to resistivity measurements, from which the carrier density can be obtained only with an assumed model for the temperature dependence of the mobility. Finally, in some cases defect levels are extracted from steady-state photo-EPR, the limitations of which were outlined earlier. Nevertheless, the EPR and electrical studies of these compensating centers have generated a great deal of information on which to further advance the growth and characterization of SiC.

Fig. 45.24 Concentration of the P6, P7 centers versus concentration of the Z1/Z2 defect measured in the different samples indicated on the graph. The solid line represents a 1 : 1 correlation; the dashed line is a straight line fit (after [45.68])

With more time, the true nature of the compensating defect(s) may be revealed.

Interface Defects and Defect Level

One last study that deserves mention is the association of electrically detected states at the interface between Si and SiO₂ with the Si P_b center [45.39]. Unique among all the investigations described thus far, the interface

Fig. 45.25 Interface-state density peaks obtained from an oxidized Si sample measured in situ during an EPR measurement (after [45.39], © AIP 1984)

Fig. 45.26 Concentration of P_b centers obtained from EPR measurements made on the same sample as in Fig. 45.25 (after [45.39], © AIP 1984)

state–P_b center correlation was performed in situ. That is, the capacitance–voltage (C–V) measurements necessary to detect the interface states were measured on the EPR samples in the microwave cavity. In this way, sample-to-sample uncertainty was eliminated. The experiment requires special sample preparation because metal layers necessary for electrical contact severely reduce EPR sensitivity. The investigators soldered wires to a thick, 0.0028 cm² contact pad that was positioned adjacent a 0.53 cm² thin (50 nm) contact. As a varying electrical bias was applied, the small dot was used for the C–V measurement and the large area was used for EPR. The data of Figs. 45.25 and 45.26 show the interface state density and relative change in the number of P_b centers measured at selected values of the applied bias, respectively. The *x*-axes of both figures were derived from the applied gate voltage using standard analysis, and the *y*-axis of Fig. 45.26 was extracted from the derivative of the EPR signal intensity as a function of bandgap energy [45.39, 79]. The similarity of the two data sets clearly shows that the dangling bonds at the Si–SiO₂ interface are responsible for *D*_{it} located 0.3 and 0.8 eV above *E*_v. Many other electrical measurements and annealing studies have indirectly reaffirmed this conclusion.

45.4.3 Heat Treatment and EPR

Monitoring changes in the EPR signal during heat treatment may determine many interesting properties of defects. The changes may be simply intensity changes as the defect is gradually passivated by an external species introduced during the anneal or a complete transformation of the spectrum from one type of center to another. The heat treatment may be performed either in situ from 4 to 400 K or ex situ up to any temperature desired. Keeping the sample in the cavity is a tremendous advantage during an annealing study because it avoids uncertainties due to sample alignment; however, a typical cavity can withstand heat only slightly above room temperature. Special EPR cavities are available that can be used up to 1000 °C; however the cavities are extremely expensive and found mostly at user facilities. At the opposite extreme, temperatures approaching millikelvins are achievable in an EPR system, but not on a regular basis in a typical laboratory. Luckily, many centers are observable between the temperatures easily accessible in most facilities, 4–400 K.

The temperature range of ex situ annealing studies is limited only by the thermal properties of the sample and furnace availability. Since the sample must be re-

mounted in the cavity after each anneal, proper sample alignment is critical, but this is easily accomplished by thoughtful design of a sample holder. Another consideration in the annealing study is possible changes in the cavity quality factor Q , a measurement of the system sensitivity. The sample partially determines Q , so that any changes caused by heat treatments may change the sensitivity of the measurement and thus perturb the results. The most obvious concern is activation of shallow impurities that contribute to conductivity, one factor that affects the sensitivity of the cavity directly. To avoid confusion a standard can be mounted with the sample on the holder. The standard should contain a well-established isotropic signal with narrow line width and a g -value well separated from that of the sample. When EPR measurements are performed below the freeze-out temperature for carriers produced from shallow impurities, the sensitivity changes during the annealing study are less of a concern; nevertheless, it is good practice to include the standard during any experiment in which EPR intensities will be compared.

Another factor to consider when doing annealing studies is that the amplitude of an EPR signal is inversely proportional to the measurement temperature. This is a concern whenever spectra that are to be compared are measured at different temperatures. In this situation, one must account for the temperature dependence of the EPR signal by normalizing all spectra to a chosen temperature before analysis. The temperature dependence of an EPR signal, often referred to as the Curie law, originates from the statistical difference between spin populations in the initial and final energy levels producing the EPR transition. Boltzmann statistics states that this population difference is exponentially dependent on the temperature and the energy difference between the spin-up and spin-down states. The temperature dependence may often be approximated as $\frac{1}{T}$ because $k_B T$ is typically greater than the energy difference between the spin states. For measurements below 4 K, however, the exact expression should be used [45.1].

In situ EPR annealing studies have revealed information about the chemical kinetics among different charge states of defects as well as the mechanisms of charge transport in materials [45.54, 55, 75, 80]. The work of Merkle and Maier on the association of metal impurities with oxygen vacancies in SrTiO_3 provides an example where chemical kinetics are thoroughly analyzed using samples with different starting concentrations of impurities [45.80]. By monitoring the evolution of Fe^{3+} and Mn^{5+} with temperature, the au-

thors extracted the reaction enthalpies and entropies for the association of the metal impurities with oxygen vacancies. The EPR signals for Fe^{3+} , Mn^{5+} and the oxygen-vacancy-related species, Fe^{3+}V_0 and Mn^{5+}V_0 , were measured between room temperature and 170 K. Data analysis suggests that almost all the oxygen vacancies in Fe-doped material are bound to the iron impurities at 300 K, but the situation with the Mn is not as clear. In general, the results have interesting implications for those growing nominally pure titanate films. If the films are free of metal contaminants, will the chronic oxygen-deficiency problem associated with complex oxides be minimized or even eliminated? Such a question will remain unanswered until a sufficient quantity of films of repeatable quality is available for thorough materials characterization, including EPR.

Ex situ EPR/annealing studies range from simply noting the temperature at which an EPR signal intensity changes dramatically to a complete kinetic analysis of the chemical reactions involved in the thermal annealing process. The former do not need to be discussed here, but the latter is addressed below using the Si P_b center as an example.

A very thorough study of hydrogen release from a passivated P_b center is provided by Brower and Myer [45.81, 82]. Using (111) Si wafers oxidized to maximize the number of P_b centers, Brower measured the intensity of the EPR signal after isothermal vacuum heat treatments over a temperature range of 500 and 595 °C. The low signal-to-noise ratio prevented a more extensive temperature range. The data were found to fit a first-order kinetic equation that includes the temporal profile of the furnace and temperature-dependent rate constant. According to the model, the number of P_b centers remaining after an anneal at temperature T is

$$P_{b\text{-calc}} = N_0 \left(1 - \exp \left\{ -k_{d0} \int_{T_{\text{profile}}} \exp \left[-\frac{E_d}{k_B T}(t) \right] dt \right\} \right), \quad (45.11)$$

where k_{d0} is the first-order rate constant, E_d is the activation energy for dissociation, and N_0 is the maximum number of P_b centers measured by EPR. The analysis proceeded as follows. First, k_{d0} was obtained from a fit to the time evolution of the P_b center at a fixed temperature. The rate constants obtained from a range of temperatures were then fitted to a first-order kinetic equation to obtain E_d . The k_{d0} and E_d values were then used in (45.11) to determine $P_{b\text{-calc}}$. Figure 45.27 shows agreement between the values calculated us-

Fig. 45.27 Fraction of P_b centers calculated using (45.11) versus fractional P_b density measured after hydrogenation and subsequent vacuum annealing. The *straight line* represents a 1 : 1 correspondence (after [45.82])

Fig. 45.28 Fraction of P_b centers calculated using (45.11) versus fractional P_b density measured after deuterium heat treatment and subsequent vacuum annealing. The *straight line* represents a 1 : 1 correspondence (after [45.82])

ing (45.11) and the experimental data points obtained between 500 and 595 °C. Figure 45.28 shows that similarly good agreement was obtained when D_2 instead of H_2 was released from the interface by the vacuum annealing process. The deuterium study provided support for the involvement of hydrogen in the annealing process in that the ratio of the k_{d0} values extracted from the H_2 and D_2 data agreed with that expected from the different vibrational frequencies for hydrogen and deuterium. Complete analysis of the data yields val-

ues of $k_{d0} = 1.2 \times 10^{12} \text{ s}^{-1}$ and $E_d = 2.56 \pm 0.06 \text{ eV}$ for the dissociation process $P_bH \rightarrow P_b + H$. Earlier studies of the passivation process $P_b + H \rightarrow P_bH$ had yielded $E_d = 1.66 \pm 0.06 \text{ eV}$. Brower used both sets of values to describe the dissociation of H_2 in semiconductors. Similar studies involving passivation of donors and acceptors in semiconductors exist in the literature [45.71, 75, 76]. Most are not as thorough as the one described here, but all provide insight into the chemical entities involved in the annealing treatments.

45.5 Summary and Final Thoughts

Electron paramagnetic resonance spectroscopy ultimately determines the spin wavefunction by probing the Δm_s transitions at paramagnetic defects. After intensive measurement and analysis, which often includes a comparison with theoretical calculations, a picture of a defect emerges including the identity of the nucleus (nuclei), symmetry, charge state, and absolute number of defects. The experimental procedure may be summarized as follows. A spectrum is obtained by placing a sample in a bath of 10 GHz microwaves situated between the poles of an electromagnet. The magnetic field

is ramped to remove the spin degeneracy of the ground state. When the energy difference between the m_s levels equals that of the microwave energy, the sample absorbs the microwaves and this absorption is detected by the external circuitry. The spectrum reflects the derivative of the absorption because the ramped magnetic field is modulated. Phase-sensitive detection is used to monitor the microwave intensity returned from the sample.

Once a spectrum is obtained, it can be interpreted in terms of the Zeeman, nuclear hyperfine, and nuclear

fine-structure terms as shown in (45.9). The g -value is determined from the first term and zero crossing of the EPR signal, and the angular dependence of g establishes the symmetry of the center. The second term relates directly to the nuclei that are involved in the defect. The number of hyperfine lines and their intensity is determined by the spin and isotopic abundance of the nucleus. This is often enough to identify the chemical elements forming the defect. Together with the angular dependence of the separation between the hyperfine lines, data may be compared with theory to establish the defect structure and charge state. Additional information is obtained from the fine-structure term, which reflects the spin multiplicity and can sometimes directly determine the charge state of the center. Although not every defect provides all this information, many may be thoroughly described by their electron paramagnetic resonance spectrum, as is illustrated many times throughout this chapter.

Throughout the past five decades, multitudes of intensive investigations have identified intrinsic defects and impurities in semiconductors and insulators. Often, a spectrum measured from a newly obtained sample is easily identified after a reasonable literature search. With the type of defect known, additional experiments may be performed to determine other parameters such as defect level, transport mechanisms or dissociation energy. Examples of such studies are discussed throughout this chapter.

Finally, the reader should be made aware of the many sophisticated versions of magnetic resonance that are not described in this chapter. The most powerful for determining defect structure is electron nuclear double resonance (ENDOR). Developed by Feher in the early 1950s, the technique allows for direct detection of the nucleus by monitoring the nuclear spin flips during an EPR experiment. The technique avoids the

ambiguity often encountered when measuring hyperfine line intensities by monitoring the nuclear resonance directly. Because the sensitivity of ENDOR is lower than that of EPR, films are rarely measured. On the other hand, a variation of magnetic resonance that monitors the change in luminescence when sweeping through the resonance field is ideal for studying small samples. Optically detected magnetic resonance (ODMR) combines the spectroscopic selectivity of EPR with the high sensitivity of photoluminescence. ODMR uses the applied magnetic field to flip the electron spin, so that previously spin-forbidden electronic transitions become allowed or allowed transitions become spin-forbidden. Basically, one excites the sample at a luminescence peak and ramps the magnetic field through resonance, causing the peak to increase or decrease depending on the exact nature of the transition. A second technique that is amenable to thin films is electrically detected magnetic resonance (EDMR). An electron-hole recombination current is monitored while the magnetic field is ramped through resonance. When the spins flip, the current changes because the electron-hole recombination transition is controlled by spin selection rules. Although most of the spectroscopic information is lost in the generally broadened signals, the high sensitivity of EDMR allows for studies of interfaces in a transistor-type structure. Thus, the technique is invaluable if direct comparison with electronic device characteristics is desired. Additional variations on EPR exist, including measurements in the time domain. However such pulsed-EPR techniques are seldom applied to crystals and are not typically classified as *materials characterization* techniques because of their inherent complexity and the fundamental nature of the information extracted. All of the magnetic resonance methods mentioned in this closing comment are outlined in [45.1], where further details may be obtained.

46. Defect Characterization in Semiconductors with Positron Annihilation Spectroscopy

Filip Tuomisto

Positron annihilation spectroscopy is an experimental technique that allows the selective detection of vacancy defects in semiconductors, providing a means to both identify and quantify them. This chapter gives an introduction to the principles of the positron annihilation techniques and then discusses the physics of some interesting observations on vacancy defects related to growth and doping of semiconductors. Illustrative examples are selected from studies performed in silicon, III-nitrides, and ZnO.

A short overview of positron annihilation spectroscopy is given in Sect. 46.1. The identification of vacancies and their charge states is described in Sect. 46.2; this section also discusses how ion-type acceptors can be detected due to the positrons' shallow Rydberg states around negative ions. The role of vacancies in the electrical deactivation of dopants is discussed in Sect. 46.3, and investigations of the effects of growth conditions on the formation of vacancy defects are reviewed in Sect. 46.4. Section 46.5 gives a brief summary.

-------------------------	------

Many techniques are applied to identify defects in semiconductors on the atomic scale. The role of the positron annihilation method is due to its ability to selectively detect vacancy-type defects. This is based on two special properties of the positron: it has a positive charge and it annihilates with electrons. An energetic positron which has penetrated into a solid rapidly loses its energy and then lives a few hundred picoseconds in thermal equilibrium with the environment. During its thermal motion the positron interacts with defects, which may lead to trapping into a localized state. Thus the final

positron annihilation with an electron can happen from various states.

Energy and momentum are conserved in the annihilation process, where two photons of about 511 keV are emitted in opposite directions. These photons carry information on the state of the annihilated positron. The positron lifetime is inversely proportional to the electron density encountered by the positron. The momentum of the annihilated electron causes an angular deviation from the 180° straight angle between the two 511 keV photons and creates a Doppler shift in their energy. Thus

the observation of positron annihilation radiation gives experimental information on the electronic and defect structures of solids.

The sensitivity of positron annihilation spectroscopy to vacancy-type defects is easy to understand. The free positron in a crystal lattice feels strong repulsion from the positive ion cores. An open-volume defect such as a vacant lattice site is therefore an attractive center where the positron gets trapped. The reduced electron density at the vacant site increases the positron lifetime. In addition, the missing valence and core electrons cause substantial changes in the momentum distribution of the annihilated electrons. Two positron techniques have been efficiently used in defect studies in semiconductors, namely the positron lifetime and the Doppler broadening of the 511 keV line. There are three main advantages of positron annihilation spectroscopy, which can be listed as follows. First, the identification of vacancy-type defects is straightforward. Second, the technique is strongly supported by theory, since the annihilation characteristics can be calculated from first principles. Finally, positron annihilation can be applied to bulk crystals and thin layers of any electrical conduction type.

The experimental and theoretical bases of the positron annihilation spectroscopy of vacancies in metals and alloys were developed in the 1970s. Its applications started gradually to widen to semiconductors in the beginning of the 1980s. At that time the low-energy positron beam was also developed and opened an avenue for defect studies of epitaxial layers and surface regions. The positron annihilation method

has had a significant impact on defect spectroscopy in solids by introducing an experimental technique for the unambiguous identification of vacancies. Native vacancies have been observed at high concentrations in many compound semiconductors, and their role in doping and compensation can now be quantitatively discussed.

In addition to vacancy defects, positrons may become confined to interesting regions of low-dimensional structures in semiconductors such as quantum wells, heterointerfaces and quantum dots due to favorable affinity or internal electric fields. The annihilation radiation carries information on the details of the electronic and atomic structures and the chemical composition of the annihilation site. We will, however, in this chapter concentrate on studies of vacancy defects which combined with, e.g., electrical measurements provide quantitative information on electrical compensation.

The aim of this chapter is twofold. We first want to introduce the principles of the positron annihilation techniques and then to discuss the physics of some interesting observations on vacancy defects related to growth and doping of semiconductors. For the sake of coherence, the illustrative examples are selected from the studies performed by the positron group of the Helsinki University of Technology in Si, III-nitrides, and ZnO. For full information on all the published works on positron annihilation in semiconductors, we refer to earlier review articles [46.1–4], books and book chapters [46.5–10], the proceedings of the International Conference on Positron Annihilation (ICPA), and other references therein.

46.1 Positron Annihilation Spectroscopy

In this section we review the principles of positron annihilation spectroscopy and describe the experimental techniques. Thermalized positrons in lattices behave like free electrons and holes. Analogously, positrons have shallow hydrogenic states at negative ions such as acceptor impurities. Furthermore, vacancies and other centers with open volume act as deep traps for positrons. These defects can be detected experimentally by measuring either the positron lifetime or the momentum density of the annihilating positron–electron pairs (Doppler broadening of the annihilation radiation). For the sake of clarity, we will concentrate on the measurements of those two quantities, as these two

methods are the most used in defect studies in semiconductors. Descriptions of other techniques can be found in, e.g., [46.9].

46.1.1 Positron Implantation and Diffusion in Solids

The basic principle of a positron experiment is shown in Fig. 46.1. Positrons are easily obtained from radioactive (β^+) isotopes such as ^{22}Na (other possible isotopes are, e.g., ^{58}Co , ^{64}Cu , and ^{68}Ge). The most commonly used isotope is ^{22}Na , where the positron emission is accompanied by a 1.27 MeV photon. This photon is used

in positron lifetime experiments as the time signal of the positron emission from the source. The stopping profile of positrons from the β^+ emission is exponential [46.6, 11]. For the ^{22}Na source, where the positron energy distribution extends to $E_{\text{max}} = 0.54 \text{ MeV}$, the positron mean stopping depth is about $110 \mu\text{m}$ in Si and $40 \mu\text{m}$ in GaN. The positrons emitted directly from a radioactive source thus probe the bulk of a solid.

Low-energy positrons are needed for studying thin overlayers and near-surface regions. Positrons from the β^+ emission are first slowed down and thermalized in a moderator. This is usually a thin film placed in front of the positron source and made of a material (e.g., Cu or W) that has a negative affinity for positrons. Thermalized positrons close to the moderator surface are emitted into the vacuum with energy of the order of 1 eV and a beam is formed using electric and magnetic fields. The positron beam is accelerated to a tunable energy of 0–40 keV, giving the possibility to control the positron stopping depth in the sample. The typical intensity of a positron beam created in this way is 10^4 – $10^6 \text{ e}^+ \text{ s}^{-1}$. Another way of producing a positron beam is through the electron–positron pair production process. This, however, requires a remarkably larger facility (e.g., a nuclear reactor) and hence not many such beams exist in spite of the advantage of obtaining a beam intensity several orders of magnitude higher than that of a conventional beam.

For monoenergetic positrons, the stopping profile can be described by a derivative of a Gaussian function, i.e., a Makhov profile, with a mean stopping depth [46.2, 11]

$$\bar{x} = 0.886x_0 = AE^n \text{ (keV)}, \quad (46.1)$$

where E is the positron energy, $A = (4/\rho)\mu\text{g}/\text{cm}^2$; $n \approx 1.6$, and ρ is the density of the material in g/cm^3 . The mean stopping depth varies with energy from 1 nm up to a few microns. A 20 keV energy corresponds to $2 \mu\text{m}$ in Si and $0.8 \mu\text{m}$ in GaN. The width of the stopping profile is rather broad and hence the positron energy must be carefully chosen so that, e.g., the signal from an overlayer is not contaminated by that from the substrate or the surface.

In a solid, the fast positron rapidly loses its energy through ionization and core electron excitation. Finally, the positron momentum distribution relaxes to a Maxwell–Boltzmann distribution through electron–hole excitation and phonon emission. The thermalization time at 300 K is 1–3 ps, i.e., much less than a typical positron lifetime of 200 ps [46.12, 13]. The

Fig. 46.1 Schematic figure of a positron experiment, where the positrons are implanted into a sample from a ^{22}Na source. The positron lifetime is determined as the time difference between the 511 keV annihilation photons and the 1.27 MeV photon emitted together with the positron from ^{22}Na . The Doppler shift ΔE results from the momentum of the annihilating electron–positron pairs

positron behaves thus as a fully thermalized particle in semiconductors.

The transport of thermalized positrons in solids can be described by diffusion theory. The positron diffusion coefficient has been measured in several semiconductors by implanting low-energy positrons at various depths and observing the fraction which diffuses back to the entrance surface [46.14–16]. The diffusion coefficient D_+ at 300 K is in the range 1.5 – $3 \text{ cm}^2 \text{ s}^{-1}$. The total diffusion length during the finite positron lifetime τ is

$$L_+ = (6D_+\tau)^{1/2} \approx 5000 \text{ \AA}. \quad (46.2)$$

If defects are present, the positron may get trapped before annihilation and this naturally reduces the effective diffusion length. On the other hand, the presence of an electric field, due to, e.g., charging of the sample surface, increases the effective diffusion length.

46.1.2 Positron States and Annihilation Characteristics

Positron Wavefunction and Lifetime, and the Momentum Distribution of the Annihilation Radiation

After implantation and thermalization positrons in semiconductors behave like free carriers (i.e., the positron state is a Bloch state in a defect-free lattice). Various positron states yield specific annihilation characteristics that can be experimentally observed in positron lifetime and Doppler broadening experiments. The positron wavefunction can be calculated from the

one-particle Schrödinger equation [46.3]

$$-\frac{\hbar^2}{2m}\nabla^2\Psi_+(\mathbf{r}) + V(\mathbf{r})\Psi_+(\mathbf{r}) = E_+\Psi_+(\mathbf{r}), \quad (46.3)$$

where the positron potential consists of two parts

$$V(\mathbf{r}) = V_{\text{Coul}}(\mathbf{r}) + V_{\text{corr}}(\mathbf{r}). \quad (46.4)$$

The first term is the electrostatic Coulomb potential and the second term takes into account the electron–positron correlation effects. Many practical schemes exist for solving the positron state Ψ_+ from the Schrödinger equation [46.3, 17].

A positron state can be characterized experimentally by measuring the positron lifetime and the momentum distribution of the annihilation radiation. These quantities can also be calculated once the corresponding electronic structure of the solid system is known. The positron annihilation rate λ , the inverse of the positron lifetime τ , is proportional to the overlap of the electron and positron densities

$$1/\tau = \lambda = \pi r_0^2 c \int d\mathbf{r} |\Psi_+(\mathbf{r})|^2 n(\mathbf{r}) \gamma[n(\mathbf{r})], \quad (46.5)$$

where r_0 is the classical electron radius, c is the velocity of light, $n(\mathbf{r})$ is the electron density, and $\gamma(n)$ is the enhancement factor that accounts for the pile-up of the electron density at the positron beyond the (average) density $n(\mathbf{r})$ [46.3]. The momentum distribution $\rho(\mathbf{p})$ of the annihilation radiation is a nonlocal quantity and requires knowledge of all the electron wavefunctions Ψ_i overlapping with the positron. It can be written in the form

$$\rho(\mathbf{p}) = \frac{\pi r_0 c}{V} \sum_i \left| \int d\mathbf{r} e^{-i\mathbf{p}\cdot\mathbf{r}} \Psi_+(\mathbf{r}) \Psi_i(\mathbf{r}) \sqrt{\gamma_i(\mathbf{r})} \right|^2, \quad (46.6)$$

where V is the normalization volume and $\gamma_i(\mathbf{r})$ may depend only on i or on \mathbf{r} . A Doppler broadening experiment measures the longitudinal momentum distribution along the direction of the emitted 511 keV photons, defined here as the z -axis

$$\rho(p_L) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} dp_x dp_y \rho(\mathbf{p}). \quad (46.7)$$

It should be noted that the momentum distribution $\rho(\mathbf{p})$ of the annihilation radiation is mainly that of the annihilating electrons *seen by the positron*, because the momentum of the thermalized positron is negligible.

Fig. 46.2 Delocalized positron density in a perfect ZnO lattice according to theoretical calculations. The c -axis of the wurtzite structure is in the *vertical direction* in the figure plane. The positions of the Zn and O atoms are marked with *larger and smaller thick open circles*, respectively. The contour spacing is $1/7$ of the maximum value, the *darkest line denoting the highest value*

As an example, the calculated positron density in a perfect ZnO wurtzite lattice is shown in Fig. 46.2. For details of the calculations see [46.18]. The positron is delocalized in a Bloch state with $k_+ = 0$. Due to the Coulomb repulsion by positive ion cores, the positron wavefunction has its maximum at the interstitial space between the atoms. The positron energy band $E_+(\mathbf{k})$ is parabolic and free-particle-like with an effective mass of $m^* \approx 1.1 m_0$ [46.3].

Deep Positron States at Vacancy Defects

In analogy to free carriers, also the positron has localized states at lattice imperfections. At vacancy-type defects where ions are missing, the repulsion sensed by the positron is lowered and the positron feels these kinds of defects as potential wells. As a result, localized positron states at open-volume defects are formed. The positron ground state at a vacancy-type defect is generally deep: the binding energy is about 1 eV or more [46.3]. Figure 46.3 shows the calculated density of the localized positron at unrelaxed Zn and O vacancies in ZnO. The positron wavefunction is confined in the open volume formed at the vacancy. The localiza-

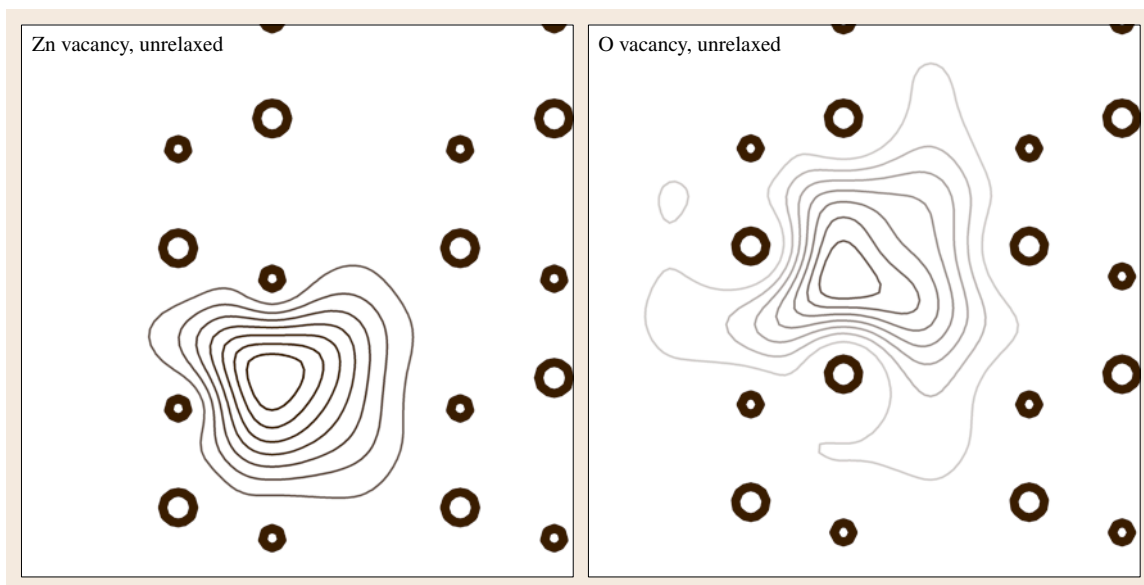

Fig. 46.3 Localized positron density in a perfect ZnO lattice according to theoretical calculations. The c -axis of the wurtzite structure is in the vertical direction in the figure plane. The positions of the Zn and O atoms are marked with larger and smaller thick open circles, respectively. The contour spacing is $1/7$ of the maximum value, the darkest line denoting the highest value

tion is clearly stronger in the case of the Zn vacancy because the open volume of V_{Zn} is much larger than that of V_{O} .

In a vacancy defect the electron density is locally reduced. This is reflected in the positron lifetimes, which are longer than in the defect-free lattice. For example, the calculated lifetimes in the unrelaxed Zn and O vacancies are 45 ps and 3 ps longer than in the perfect lattice. The longer positron lifetime at V_{Zn} is due to the larger open volume compared with that of V_{O} . The positron lifetime measurement is thus a probe of vacancy defects in materials. Positron annihilation at a vacancy-type defect leads also to changes in the momentum distribution $\rho(\mathbf{p})$ probed by the Doppler broadening experiment. The momentum distribution arising from valence electron annihilation becomes narrower due to a lower electron density. In addition, the localized positron at a vacancy has a reduced overlap with ion cores, leading to a considerable decrease in annihilation with high-momentum core electrons. In our model case of ZnO, where the dominant contribution to the high-momentum part of the distribution comes from the Zn 3d electrons, the changes in the momentum distribution are more pronounced when positrons are trapped at Zn vacancies.

The comparison of the measured positron lifetimes and Doppler broadening spectra with the theoretically calculated data for specific defects provides a very efficient tool for identification of the observed vacancy defects. Several *ab initio* approaches have been studied in recent years [46.17, and the references therein]. The agreement between theory and experiment is excellent in terms of differences or ratios between the data for defects and the perfect lattice. Also quantitative agreement has been obtained in many materials, but all the theoretical schemes applied so far seem to have problems with the treatment of 3d electrons, either under- or overestimating their contribution to the positron annihilation data. For example, in the case of ZnO, the calculated lifetimes in the perfect lattice range from about 140 to 180 ps [46.19, 20], depending on the scheme, while the experimentally determined bulk lifetime is 170 ps [46.20, 21]. On the other hand, the calculated differences in the lifetimes and the ratios of the momentum distributions between the defect and bulk states agree very well with experiments [46.17, 20, 22].

Shallow Positron States at Negative Ions

A negatively charged impurity atom or an intrinsic point defect can bind positrons at shallow states even if these

defects do not contain open volume [46.23, 24]. Being a positive particle, the positron can be localized at the hydrogenic (Rydberg) state of the Coulomb field around a negatively charged center. The situation is analogous to the binding of an electron to a shallow donor atom. The positron binding energy at the negative ion can be estimated from the simple effective-mass theory

$$E_{\text{ion},n} = \frac{13.6 \text{ eV}}{\varepsilon^2} \left(\frac{m^*}{m_0} \right) \frac{Z^2}{n^2} \approx 10\text{--}100 \text{ meV}, \quad (46.8)$$

where ε is the dielectric constant, m^* is the effective mass of the positron, Z is the charge of the negative ion, and n is the quantum number. With $m^* \approx m_0$, $Z = 1\text{--}3$, and $n = 1\text{--}4$, (46.8) yields typically $E_{\text{ion}} = 10\text{--}100 \text{ meV}$, indicating that positrons are thermally desorbed from the Rydberg states at 100–300 K.

The hydrogenic positron state around a negative ion has a typical extension of 10–100 Å and thus positrons probe the same electron density as in the defect-free lattice. As a consequence, the annihilation characteristics (positron lifetime, positron–electron momentum distribution) are not different from those in the lattice. Although the negative ions cannot be identified with the experimental parameters, information on their concentration can be obtained in the positron lifetime and Doppler broadening experiments when they compete with vacancies in positron trapping [46.23, 24].

46.1.3 Positron Trapping at Point Defects

Positron Trapping Rate and Trapping Coefficient

The positron transition from a free Bloch state to a localized state at a defect is called positron trapping. The trapping is analogous to carrier capture. However, it must be fast enough to compete with annihilation. The positron trapping rate κ onto a defect D is proportional to the defect concentration c_D

$$\kappa_D = \mu_D c_D. \quad (46.9)$$

The trapping coefficient μ_D depends on the defect and the host lattice. Since the positron binding energy at vacancies is typically $> 1 \text{ eV}$, the thermal escape (detrapping) of positrons from the vacancies can usually be neglected. Due to the Coulomb repulsion, the trapping coefficient at positively charged vacancies is so small that the trapping does not occur during the short positron lifetime of a few hundred picoseconds [46.25]. Therefore, the positron technique does

not detect vacancies or other defects in their positive charge states. The trapping coefficient at neutral vacancies is typically $\mu_D \approx 10^{14}\text{--}10^{15} \text{ s}^{-1}$ independently of temperature [46.25–27]. This value means that neutral vacancies are observed when their concentration is $\geq 10^{16} \text{ cm}^{-3}$.

The positron trapping coefficient at negative vacancies is typically $\mu_D \approx 10^{15}\text{--}10^{16} \text{ s}^{-1}$ at 300 K temperature [46.25–27]. The sensitivity to detect negative vacancies is thus $\geq 10^{15} \text{ cm}^{-3}$. The experimental fingerprint of a negative vacancy is the increase of μ_D with decreasing temperature [46.26, 27]. The $T^{-1/2}$ dependence of μ_D is simply due to the increase of the amplitude of the free positron Coulomb wave in the presence of a negative defect as the thermal velocity of the positron decreases [46.25]. The temperature dependence of μ_D allows to experimentally distinguish negative vacancy defects from neutral ones.

The positron trapping coefficient μ_{ion} at the hydrogenic states around negative ions is of the same order of magnitude as that at negative vacancies [46.24, 28]. Furthermore, the trapping coefficient exhibits a similar $T^{-1/2}$ temperature dependence. Unlike in the case of vacancy defects, the thermal escape of positrons from the negative ions plays a crucial role at usual experimental temperatures. The principle of detailed balance yields the following equation for the detrapping rate δ_{ion} from the hydrogenic state [46.3]

$$\delta_{\text{ion}} = \mu_{\text{ion}} \left(\frac{2\pi m^* k_B T}{h^2} \right)^{3/2} \exp \left(-\frac{E_{\text{ion}}}{k_B T} \right). \quad (46.10)$$

Typically ion concentrations above 10^{16} cm^{-3} influence positron annihilation at low temperatures ($T < 100 \text{ K}$), but the ions are not observed at high temperatures ($T > 300 \text{ K}$), where the detrapping rate (46.10) is large.

Kinetic Trapping Model

In practice the positron annihilation data is analyzed in terms of kinetic rate equations describing the positron transitions between the free Bloch states and localized states at defects [46.8–10]. Very often the experimental data show the presence of two defects, one of which is a vacancy and the other is a negative ion. The probability of a positron to be in the free state is $n_B(t)$, to be trapped at vacancies is $n_V(t)$, and to be trapped at ions is $n_{\text{ion}}(t)$. We can write the rate equations as

$$\frac{dn_B}{dt} = -(\lambda_B + \kappa_V + \kappa_{\text{ion}}) n_B + \delta_{\text{ion}} n_{\text{ion}}, \quad (46.11)$$

$$\frac{dn_V}{dt} = \kappa_V n_B - \lambda_V n_V, \quad (46.12)$$

$$\frac{dn_{ion}}{dt} = \kappa_{ion} n_B - (\lambda_{ion} + \delta_{ion}) n_{ion}, \quad (46.13)$$

where λ , κ , and δ refer to the corresponding annihilation, trapping, and detrapping rates.

Assuming that the positron at $t = 0$ is in the free Bloch state, (46.11–46.13) can be solved and the probability of a positron to be alive at time t is obtained as

$$n(t) = n_B(t) + n_V(t) + n_{ion}(t) = \sum_{i=1}^3 I_i \exp(-\lambda_i t), \quad (46.14)$$

indicating that the lifetime spectrum $-dn(t)/dt$ has three exponential components. The fractions of positron annihilations at various states are

$$\eta_B = \int_0^\infty dt \lambda_B n_B(t) = 1 - \eta_{ion} - \eta_V, \quad (46.15)$$

$$\eta_V = \int_0^\infty dt \lambda_V n_V(t) = \frac{\kappa_V}{\lambda_B + \kappa_V + \frac{\kappa_{ion}}{1 + \delta_{ion}/\lambda_{ion}}}, \quad (46.16)$$

$$\begin{aligned} \eta_{ion} &= \int_0^\infty dt \lambda_{ion} n_{ion}(t) \\ &= \frac{\kappa_{ion}}{(1 + \delta_{ion}/\lambda_{ion}) \left(\lambda_B + \kappa_V + \frac{\kappa_{ion}}{1 + \delta_{ion}/\lambda_{ion}} \right)}. \end{aligned} \quad (46.17)$$

These equations are useful because they can be related with the experimental average lifetime τ_{ave} (the center of mass of the lifetime spectrum), the positron–electron momentum distribution $\rho(p_L)$, and the shape parameters S and W of the Doppler-broadened annihilation line (representing annihilations with low-momentum valence electrons and high-momentum core electrons, respectively) as follows

$$\tau_{ave} = \eta_B \tau_B + \eta_{ion} \tau_{ion} + \eta_V \tau_V, \quad (46.18)$$

$$\rho(p_L) = \eta_B \rho_B(p_L) + \eta_{ion} \rho_{ion}(p_L) + \eta_V \rho_V(p_L), \quad (46.19)$$

$$S = \eta_B S_B + \eta_{ion} S_{ion} + \eta_V S_V, \quad (46.20)$$

$$W = \eta_B W_B + \eta_{ion} W_{ion} + \eta_V W_V. \quad (46.21)$$

Equations (46.15–46.21) allow the experimental determination of the trapping rates κ_V and κ_{ion} , and

consequently the defect concentrations can be obtained from (46.12). Furthermore, these equations enable the combination of positron lifetime and Doppler broadening results, and various correlations between τ_{ave} , $\rho(p_L)$, S , and W can be studied.

At high temperatures all positrons escape from the hydrogenic state of the negative ions and no annihilations take place at them. In this case the lifetime spectrum has two components

$$\tau_1^{-1} = \tau_B^{-1} + \kappa_V, \quad (46.22)$$

$$\tau_2 = \tau_V, \quad (46.23)$$

$$I_2 = 1 - I_1 = \frac{\kappa_V}{\kappa_V + \lambda_B - \lambda_D}. \quad (46.24)$$

The first lifetime τ_1 represents the effective lifetime in the lattice in the presence of positron trapping at vacancies. Since $\kappa_V > 0$ and $I_2 > 0$, τ_1 is less than τ_B . The second lifetime component τ_2 characterizes positrons trapped at vacancies, and it can be directly used to identify the open volume of the vacancy defect. When $\eta_{ion} = 0$ and $\delta_{ion}/\lambda_{ion} \gg 1$ the determination of the positron trapping rate and vacancy concentration is straightforward using (46.15–46.21)

$$\begin{aligned} \kappa_V &= \mu_V \kappa_V = \lambda_B \frac{\tau_{ave} - \tau_B}{\tau_V - \tau_{ave}} \\ &= \lambda_B \frac{S - S_B}{S_V - S} = \lambda_B \frac{W - W_B}{W_V - W}. \end{aligned} \quad (46.25)$$

Notice that in this case τ_{ave} , S , and W depend linearly on each other. The linearity of experimental points in (τ_{ave}, S) , (τ_{ave}, W) , and (S, W) plots thus provides evidence that positrons annihilate from two distinguishable states, indicating that they are trapped at only a single type of vacancy defect in the samples.

4.6.1.4 Experimental Techniques

Positron Lifetime Spectroscopy

Positron lifetime spectroscopy is a powerful technique in defect studies, because the various positron states appear as different exponential decay components. The number of positron states, and their annihilation rates and relative intensities can be determined. In a positron lifetime measurement, one needs to detect the start and stop signals corresponding to the positron entrance and annihilation times in the sample, respectively (Fig. 46.1). A suitable start signal is the 1.27 MeV photon that accompanies the positron emission from the ^{22}Na isotope. The 511 keV annihilation photon serves as the stop signal. The positron source is prepared by

sealing about $10\ \mu\text{Ci}$ (about $10^5\text{--}10^6\ \text{Bq}$) of radioactive isotope between two thin foils. The source is then sandwiched between two identical pieces (e.g., $5\times 5\times 0.5\ \text{mm}^3$) of the sample material. This technique is standard for bulk crystal studies. Pulsed positron beams have been constructed for lifetime spectroscopy in thin layers [46.29, 30], but so far they have not been used much in defect studies.

The conventional lifetime spectrometer consists of start and stop detectors, each of them made by coupling a fast scintillator to a photomultiplier. The timing pulses are obtained by differential constant-fraction discrimination. The time delays between the start and stop signals are converted into amplitude pulses, the heights of which are stored in a multichannel analyzer. Thanks to the development of fast analog-to-digital converters (ADCs), digital data readout techniques have recently become viable [46.31–34]. This allows direct digitization of the detector pulses and performance of the timing and energy windowing with software instead of the conventional analog electronics, simplifying the measurement setup significantly. About 10^6 lifetime events are recorded in 1 h. The experimental spectrum represents the probability of positron annihilation at time t and it consists of exponential decay components

$$-\frac{dn(t)}{dt} = \sum_i I_i \lambda_i \exp(-\lambda_i t), \quad (46.26)$$

where $n(t)$ is the probability for the positron to be alive at time t . The decay constants $\lambda_i = 1/\tau_i$ are called the annihilation rates and they are the inverses of the positron lifetimes τ_i . Each positron lifetime has intensity I_i . In practice the ideal spectrum of (46.26) is convoluted by a Gaussian resolution function which has a width of 200–250 ps (full-width at half-maximum, FWHM). About 5–10% of positrons annihilate in the source material and proper *source corrections* must be made. Due to the finite time resolution, annihilations in the source materials, and random background, typically only 1–3 lifetime components can be resolved in the analysis of the experimental spectra. The separation of two lifetimes is successful only if the ratio λ_1/λ_2 is $\geq 1.3\text{--}1.5$.

Figure 46.4 shows positron lifetime spectra recorded in as-grown and electron-irradiated high-quality ZnO bulk crystals [46.21, 35]. Positrons enter the sample and thermalize at time $t = 0$. The vertical axis of Fig. 46.4 gives the number of annihilations at a time interval of 25 ps. In the as-grown sample the positron lifetime spectrum has a single component of $170 \pm$

Fig. 46.4 Examples of positron lifetime spectra in as-grown and electron-irradiated high-quality ZnO samples. A constant background and annihilations in the source materials have been subtracted from the spectra, which consist of 2×10^6 recorded annihilation events. The *solid lines* are fits of the sum of exponential components convoluted with the resolution function of the spectrometer. The data in the as-grown sample was recorded at 300 K and has only a single component of 170 ± 1 ps. The spectrum in the electron-irradiated crystal was recorded at 170 K and can be decomposed into two components of $\tau_1 = 155 \pm 5$ ps, $\tau_2 = 230 \pm 10$ ps, and $I_2 = 38 \pm 5\%$

1 ps at 300 K corresponding to positron annihilations in the defect-free lattice. The electron-irradiated sample has two lifetime components, the longer of which ($\tau_2 = 230$ ps) is due to positrons annihilating when trapped at irradiation-induced Zn vacancies. For more discussion see Sect. 46.2.

The experimental results are often presented in terms of the average positron lifetime τ_{ave} , defined as

$$\tau_{\text{ave}} = \int_0^\infty dt \, t \left(-\frac{dn}{dt} \right) = \int_0^\infty dt \, n(t) = \sum_i I_i \tau_i. \quad (46.27)$$

The average lifetime is a statistically accurate parameter, because it is equal to the center of mass of the experimental lifetime spectrum. Hence it can be cor-

Fig. 46.5 Doppler broadening spectra obtained in different data collection modes. The definition of the shape parameters S and W is shown

rectly calculated from the intensity and lifetime values even if the decomposition only represents a good fit to the experimental data without any physical meaning. For example, the positron average lifetimes in the two spectra of Fig. 46.4 are 170 ps (as-grown ZnO) and 185 ps (electron-irradiated ZnO). The difference is very significant because changes below 1 ps in the average lifetime can be reliably observed in experiments.

Doppler Broadening Spectroscopy

Doppler broadening spectroscopy is often applied especially in the low-energy positron beam experiments, where lifetime spectroscopy is usually very difficult due to the missing start signal. The motion of the annihilating electron–positron pair causes a Doppler shift in the annihilation radiation (Fig. 46.1)

$$\Delta E_\gamma = \frac{1}{2} c p_L, \quad (46.28)$$

where p_L is the longitudinal momentum component of the pair in the direction of the annihilation photon emission. This causes the broadening of the 511 keV

annihilation line (Fig. 46.5). The shape of the 511 keV peak thus gives the one-dimensional momentum distribution $\rho(p_L)$ of the annihilating electron–positron pairs. A Doppler shift of 1 keV corresponds to a momentum value of $p_L = 3.91 \times 10^3 m_0 c$ (≈ 0.54 a.u.).

The Doppler broadening can be experimentally measured using a Ge gamma detector with a good energy resolution (Fig. 46.5). For measurements of bulk samples, the same source–sample sandwich is used as in the lifetime experiments. For layer studies, the positron beam hits the sample and the Doppler broadening is often monitored as a function of the beam energy. The typical resolution of a detector is around 1–1.5 keV at 500 keV. This is considerable compared with the total width of 2–3 keV of the annihilation peak, meaning that the experimental line shape is strongly influenced by the detector resolution. Therefore, various shape parameters are used to characterize the 511 keV line. Their definitions are shown in Fig. 46.5 as well.

The low-electron-momentum parameter S is defined as the ratio of the counts in the central region of the annihilation line to the total number of the counts in the line. In the same way, the high-electron-momentum parameter W is the fraction of the counts in the wing regions of the line. Due to their low momenta, mainly valence electrons contribute to the region of the S parameter. On the other hand, only core electrons have momentum values high enough to contribute to the W parameter. Therefore, S and W are called the valence and core annihilation parameters, respectively. The S parameter is integrated from the Gaussian part (given by the momentum distribution of the unbound or only weakly bound valence electrons) so that it includes roughly 50% of the total counts in the peak. The lower limit of the W parameter window is chosen so that the dominant contribution to that part of the spectrum comes from the exponential tails (linear in the semi-log plot) of the core electron distributions. In order to have as good statistics as possible, the upper limit is set as high as reasonable from the data scatter point of view. The proper choice of the lower limit of the W parameter window depends on the studied material.

The high-momentum part of the Doppler broadening spectrum arises from annihilations with core electrons which contain information on the chemical identity of the atoms. Thus detailed investigation of core electron annihilation can reveal the nature of the atoms in the regions where positrons annihilate. In order to study the high-momentum part in detail, the experimental background needs to be reduced. A second gamma detector is placed opposite to the Ge detector and the

only events that are accepted are those for which both 511 keV photons are detected [46.36, 37]. Depending on the type of the second detector, electron momenta

even up to $p \approx 60 \times 10^{-3} m_0 c$ (≈ 8 a.u.) can be measured with the coincidence detection of the Doppler broadening.

46.2 Identification of Point Defects and Their Charge States

The annihilation characteristics of trapped positrons serve as fingerprints in defect identification. The positron lifetime at a defect is a basic quantity for two reasons: it reflects the open volume of the defect and it can be predicted by theoretical calculations. However, the lifetime experiment alone is not enough for the direct identification of the sublattice of the vacancy in compound semiconductors or to determine whether the vacancy is isolated or complexed with impurity atoms, as it is insensitive to the chemical surroundings of the defect. Doppler broadening experiments provide information on the momentum distribution of the annihilating electrons. By the coincidence technique one can reveal the core electron momentum distribution that carries information about the type of atoms in the region of annihilation. In the case of a vacancy, the positron wavefunction is localized and overlaps predominantly with the core electrons of the neighboring atoms. Therefore, vacancies on different sublattices can be distinguished and impurities associated with vacancies may be identified. Finally, by varying the sample temperature during the experiments, one can distinguish between neutral and negative charge states of the vacancies due to the different thermal behavior of the positron trapping, and detect negatively charged non-open volume defects.

46.2.1 Vacancies in Si: Impurity Decoration

To illustrate how the positron lifetime together with Doppler broadening experiments can be used to identify vacancy defects, we review here results obtained in highly n-type Si doped with phosphorus (P) and arsenic (As). Electron irradiation with energies of the order of 1–2 MeV is a convenient experimental approach to produce a controlled concentration of vacancies. By changing the fluence one can vary the fraction of positrons annihilating at vacancies. Electron irradiation at 2 MeV creates vacancies and interstitials as primary defects, both of which are mobile in Si at 300 K [46.39]. Hence the vacancies produced in the irradiation disappear, e.g., by recombination with interstitials or by diffusion to the surface, or become stabilized by impuri-

ties or intrinsic defects, such as other vacancies. As both the vacancies and interstitials are mobile, the recombination and divacancy formation processes are not very efficient; in experiments about 1% of the primarily created vacancies have been observed to form divacancies when competing stabilizing defects, such as oxygen or dopant atoms (e.g., P or As), are not present [46.40].

Fig. 46.6 Positron lifetime spectra in as-grown and 2 MeV electron-irradiated Si samples. Positrons annihilate in the as-grown sample with a single lifetime of 220 ps corresponding to delocalized positrons in the lattice. In the irradiated samples the experiments reveal vacancies with positron lifetimes of 250 ps (V–As pair in CZ Si:As sample doped with $[As] = 1020 \text{ cm}^{-3}$) and 300 ps (divacancy in undoped FZ Si sample) [46.38]. To illustrate the sensitivity of the lifetime measurement, data measured in a p-type SiC reference sample (single lifetime component of 150 ps) and a high-temperature-annealed n-type SiC sample (two components, of which the higher is 450 ps) are shown [46.38]

Figure 46.6 shows the positron lifetime spectra measured in unirradiated float-zone (FZ)-refined Si, electron-irradiated As-doped Czochralski (CZ)-grown Si ($[As] = 10^{20} \text{ cm}^{-3}$), and electron-irradiated FZ Si samples [46.38]. To illustrate the sensitivity of the lifetime measurement, data measured in a p-type SiC reference sample (single lifetime component of 150 ps) and a high-temperature-annealed n-type SiC sample (two components, of which the higher is 450 ps) are shown [46.41]. The unirradiated samples have only a single positron lifetime component of about 220 ps, which is practically constant as a function of temperature [46.40]. This behavior shows that no vacancies are observed by positrons and all annihilations take place at the delocalized state in the bulk lattice, with the lifetime $\tau_B = 220 \text{ ps}$. The presence of vacancy defects in the electron-irradiated FZ Si samples is evident in Fig. 46.6. The lifetime spectrum has two components, the longer of which, $\tau_2 = 300 \pm 5 \text{ ps}$, corresponds to positrons trapped at vacancy defects. The lifetime of $\tau_2 = 300 \pm 5 \text{ ps}$ is significantly larger than expected for a monovacancy but it is equal to the calculated lifetime for annihilation at divacancies [46.42]. Vacancy defects are clearly present in the electron-irradiated As-doped Si samples as well (Fig. 46.6). In this case the spectrum has only a single component due to the high concentration of vacancies, causing saturation trapping of positrons. This occurs when the vacancy concentration exceeds 10^{18} cm^{-3} , consistent with the expected introduction rate in electron-irradiated heavily n-type doped Si [46.26, 27, 39]. The lifetime component is $\tau_V = 250 \pm 5 \text{ ps}$, a lifetime characteristic of a single vacancy according to theoretical calculations [46.42]. The lifetime component $\tau_V = 250 \pm 5 \text{ ps}$ is detected in as-grown As-doped Si ($[As] = 10^{20} \text{ cm}^{-3}$) as well (not shown in the figure) [46.43], but the vacancy concentration is clearly smaller than in the electron-irradiated samples. The average lifetimes are $\tau_{ave} = 232 \text{ ps}$ and $\tau_{ave} = 250 \text{ ps}$ in the as-grown and irradiated samples, respectively [46.38, 41].

In order to identify the monovacancies in detail, Doppler broadening experiments using the two-detector coincidence technique have been performed. The lifetime results from above can be used to determine the fraction of positrons annihilating at vacancies $\eta = (\tau_{ave} - \tau_B)/(\tau_V - \tau_B)$ (Sect. 46.1). Since the momentum distribution in the lattice $\rho_B(p)$ can be measured in the reference sample, the distributions $\rho_V(p)$ at vacancies can be decomposed from the measured spectrum $\rho(p)$. They are shown in Fig. 46.7 for the monovacancies observed in as-grown Si ($[As] = 10^{20} \text{ cm}^{-3}$)

Fig. 46.7 The positron–electron momentum distribution at the various vacancy–impurity pairs, identified in electron-irradiated Si ($[P] = 10^{20} \text{ cm}^{-3}$) (full circles) and in as-grown (full circles) and irradiated (open triangles) Si ($[As] = 10^{20} \text{ cm}^{-3}$). The results of the theoretical calculations are shown by the solid curves

as well as in irradiated Si ($[As] = 10^{20} \text{ cm}^{-3}$) and Si ($[P] = 10^{20} \text{ cm}^{-3}$).

The momentum distributions $\rho_V(p)$ at vacancies indicate large differences at higher momenta ($p > 1.8 \text{ a.u.}$), where annihilation with core electrons is the most important contribution (Fig. 46.7). Since the core electron momentum distribution is a specific characteristic of a given atom, the differences between the spectra indicate different atomic environments of the vacancy in each of the three cases. Because in both Si ($Z = 14$) and P ($Z = 15$) the 2p electrons constitute the outermost core electron shell, the core electron momentum distributions of these elements are very similar. The crucial difference in the core electron structures of Si, P, and As is the presence of 3d electrons in As. The overlap of positrons with the As 3d electrons is much stronger than with the more localized Si or P 2p electrons. The large intensity of the core electron momentum distribution is thus a clear sign of As atoms surrounding the vacancy.

The 2 MeV electron irradiation creates vacancies and interstitials as primary defects, both of which are mobile at 300 K. In heavily n-type Si the donor atom may capture the vacancy and form a vacancy–impurity

pair [46.39]. The monovacancy detected in heavily P-doped Si is thus the V-P pair. Similarly, it is natural to associate the electron irradiation-induced vacancy in Si([As] = 10^{20} cm^{-3}) with a V-As pair. The influence of As next to the vacancy is clearly visible as the enhanced intensity in the high-momentum region (Fig. 46.7). An even stronger signal from As is seen in the as-grown Si([As] = 10^{20} cm^{-3}). A linear extrapolation of the intensity of the distribution shows that the native complex is V-As₃, i.e., the vacancy is surrounded by *three* As atoms.

The identifications are confirmed by theoretical results [46.42, 43], which are in very good agreement at both low and high momenta. The theory reproduces the linear increase of the intensity of the core electron momentum distribution with increasing number of As atoms surrounding the vacancy. For the V-As₃ complex the agreement with the experimental result is excellent (Fig. 46.7), whereas the intensities calculated for V-As₂ and V-As₄ are much too small or large, respectively. In the valence electron momentum range, the calculated curves for V-As and V-As₃ also fit very well with the experiment. To conclude, the theoretical calculations strongly support the experimental defect identifications that (i) vacancies complexed with a single donor impurities are detected in electron-irradiated P- and As-doped Si, and (ii) the native defect in Si([As] = 10^{20} cm^{-3}) is a vacancy surrounded by three As atoms.

46.2.2 Vacancies in ZnO: Sublattice and Charge State

The elemental sensitivity of the Doppler broadening spectrum demonstrated above can be helpful in the identification of the sublattice of a vacancy in a binary compound. Under certain conditions, vacancies complexed with impurities can be distinguished from isolated vacancies also in compound semiconductors [46.44]. In materials such as GaN and ZnO, where the group III–II element is significantly heavier (and larger) than the rather light group V–VI element, already the positron lifetime experiments often give conclusive identification of the group III–II vacancies, and the differences in the Doppler spectra are pronounced. On the other hand, it is not evident that the group V–VI vacancies are detected at all. In materials such as GaAs or ZnSe, in which the two elements are quite similar, vacancies on both sublattices are more likely to trap positrons, but the differences between the vacancy-specific parameters can be quite subtle [46.8].

The lifetime in the defect-free ZnO lattice has been measured to be about 170 ps. After 2 MeV electron irradiation at room temperature a longer lifetime component $\tau_2 = 230 \pm 10 \text{ ps}$ is detected in the measured spectrum (Fig. 46.4). In addition, the average lifetime increases to $\tau_{\text{ave}} = 178 \text{ ps}$ at room temperature and up to 185 ps at lower temperatures. The longer lifetime component can be directly associated with Zn vacancies based on comparison to theoretical calculations that predict a difference of 60 ps between the Zn vacancy and the bulk lifetimes, when lattice relaxations around the vacancy are taken into account [46.20]. On the other hand, the positron lifetime in the O vacancy, even with a strong outward relaxation, would be at most 20–25 ps longer than in the bulk [46.35]. In order to put the identification on an even firmer basis, the Doppler broadening results obtained in the irradiated ZnO samples can be compared with the theoretical ones. Figure 46.8 represents both the experimental and theoretically calculated ratios of the Zn-vacancy-specific momentum distribution to that of the defect-free lattice. The experimental data for the Zn vacancy are extracted from the spectrum measured at 170 K with the help of the annihilation fractions obtained from the lifetime measurements at the same temperature in the same way as in the case of the Si vacancies in Sect. 46.2.1. The data calculated for the O vacancy are similar to those in the defect-free lattice and are not shown in the figure. The agreement between the theoretically calculated and experimentally determined ratio curves is excellent, strengthening

Fig. 46.8 Ratios curves of the experimental and theoretically calculated momentum densities specific to the Zn vacancy in ZnO

the identification of the irradiation-induced vacancy detected in ZnO as the Zn vacancy.

Figure 46.9 shows the positron lifetime measured as a function of temperature in as-grown and electron-irradiated high-quality (EaglePicher) n-type ZnO samples [46.35]. At 300–500 K the average positron lifetime in the as-grown sample is constant or very slightly increasing due to thermal expansion of the crystal lattice. It provides the lifetime of the positron in the delocalized state in the ZnO lattice, $\tau_B = 170$ ps at 300 K. The increase in the average positron lifetime with decreasing temperature at 10–300 K is a clear indication of the presence of negatively charged vacancies, the positron trapping coefficient of which increases with decreasing temperature (Sect. 46.1). A longer lifetime component of $\tau_2 = 265 \pm 25$ ps could be separated from the lifetime spectrum at 10 K, indicating that the vacancy in question is the Zn vacancy. The large un-

certainty in τ_2 is due to the fact that the increase in τ_{ave} is very small, only 3 ps (the vacancy signal is weak due to a low concentration). The same increase in the average positron lifetime with decreasing temperature at 10–300 K is observed in the data from the irradiated sample (Fig. 46.9). Here τ_{ave} is clearly above the bulk value τ_B and thus the decomposition of the lifetime spectra could be performed with much greater accuracy. The longer lifetime component is presented in the upper part of Fig. 46.9, and its average value is that specific to the Zn vacancy as discussed above, $\tau_2 = 230 \pm 10$ ps, within experimental accuracy the same as in the as-grown sample. The decrease in the average positron lifetime with decreasing temperature in the irradiated samples below 200 K is due to negative non-open volume defects (negative ions) acting as shallow traps for positrons and competing with the vacancies in trapping of positrons. Their effects are discussed in more detail in the next section.

The Doppler broadening parameters S and W , defined in Sect. 46.1, measured simultaneously with the positron lifetime fall on a line plotted against each other with temperature as the running parameter, which typically indicates the presence of only two distinguishable positron states (bulk and vacancy). The negative-ion-type defects (shallow traps) do not cause deviations from the straight line, since the annihilation parameters of positrons trapped at these defects coincide with those of the bulk. However, as can be seen in Fig. 46.10, the points measured at 90–190 K fall off the straight line determined by the annihilations in the defect-free lattice and the Zn vacancy in the (S, τ_{ave}) and (W, τ_{ave}) plots. This implies that a third positron state can be distinguished in the lifetime versus Doppler parameter data, although the Doppler data alone are linear. In order to cause a deviation from the straight line, the localization to this defect needs to be strong, implying that the defect has a distinguishable open volume. The open volume of this defect cannot be very large, since the independence of temperature of the longer lifetime component (Fig. 46.9) shows no evidence of possible mixing of several lifetime components. Hence, the lifetime specific to this defect needs to be sufficiently far from τ_2 (and closer to τ_1), below 200 ps. In addition, in order to produce the deviation from the straight line seen in Fig. 46.10, the defect-specific lifetime needs to be above τ_{ave} over the whole temperature range, i.e., above 185 ps. One additional aspect of the third type of defects is evident from the data. The fraction of positrons annihilating as trapped at this defect is vanishing at room temperature and clearly

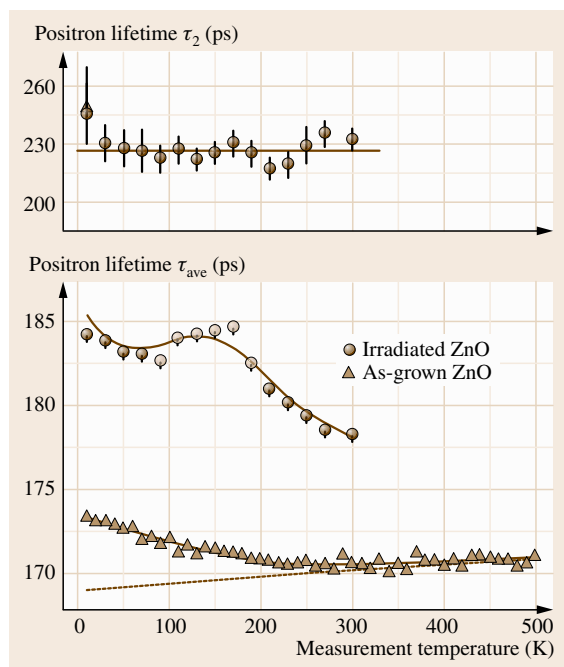

Fig. 46.9 The positron lifetime parameters of as-grown and electron-irradiated ZnO samples plotted as functions of measurement temperature. The data markers are drawn as open in the temperature range 90–190 K, where the effect of the O vacancies is the most visible. The *dashed line* shows the fitted bulk lifetime, where the temperature dependence is due to thermal expansion of the lattice. The *solid curves* represent the fitting of the temperature-dependent trapping model to the data [46.35]

smaller than the annihilation fractions at the Zn vacancies and negative-ion-type defects below 90 K, but larger at the intermediate temperature 90–190 K. This implies that the enhancement of positron trapping with decreasing temperature is larger at this defect at temperatures 190–300 K, but saturates around 150 K, where the Zn vacancies and the negative-ion-type defects become more important. This indicates that the third type of defect is neutral, and the temperature dependence of positron trapping observed at temperatures close to room temperature is due to either thermal escape from the defect or a change in the charge state (from neutral to positive) of the defect. Based on these considerations

and the lifetime value of 190–200 ps, a prominent candidate for this defect is the O vacancy that has a donor nature and would naturally have a smaller open volume than the Zn vacancy.

46.2.3 Negative Ions as Shallow Positron Traps in GaN

In addition to vacancy defects, negatively charged impurities and intrinsic defects with no open volume (called collectively negative ions), can trap positrons at shallow hydrogen-like states, as explained in Sect. 46.1. They can only be detected when they compete with vacancies in the trapping of positrons, and due to the weak localization of the positron at these defects they cannot be identified. However, their concentration can be estimated and compared with those (obtained by, e.g., secondary-ion mass spectrometry, SIMS) of the known impurities. Figure 46.11 shows a typical example of the temperature-dependent positron lifetime data when negative ions compete with vacancies in positron trapping. The data are measured in thick high nitrogen pressure (HNP)-grown bulk GaN crystals, with both the N and Ga polarity faces facing the positron source, and in thick homoepitaxial GaN layers grown with hydride vapor-phase epitaxy (HVPE) grown on both polarity faces of the bulk crystals [46.45]. All these samples are n-type.

The average positron lifetime is clearly above the bulk lifetime $\tau_B = 160 \pm 1$ ps in the HNP GaN and N-polar HVPE GaN samples (Fig. 46.11), indicating that positrons are trapped at vacancies. The lifetime spectra recorded at 300–500 K in those samples can be decomposed into two components. The positrons trapped at vacancies annihilate with the longer lifetime $\tau_V = \tau_2 = 235 \pm 10$ ps, characteristic of the Ga vacancy [46.44, 46, 47] that is negatively charged in n-type and semi-insulating GaN [46.44, 47, 48]. The average positron lifetime measured in the Ga-polar HVPE GaN samples coincides with the bulk lifetime $\tau_B = 160 \pm 1$ ps, indicating that the vacancy concentration in those samples is below the detection limit of about 10^{15} cm^{-3} .

At low temperatures the average positron lifetime in the HNP and N-polar HVPE GaN samples decreases and the lifetime at the Ga vacancy τ_V remains constant (Fig. 46.11). This behavior indicates that the fraction $\eta_V = (\tau_{\text{ave}} - \tau_B)/(\tau_V - \tau_B)$ of positrons annihilating at vacancies decreases. Since the positron trapping at negative Ga vacancies should be enhanced at low temperatures (Sect. 46.1), the decrease of η_V is due to other defects which compete with Ga vacancies as positron

Fig. 46.10 The S and W parameters measured in as-grown and electron-irradiated ZnO samples plotted as functions of τ_{ave} with temperature as the running parameter. The data markers are drawn as open in the temperature range 90–190 K, where the effect of the O vacancies is the most visible. The solid lines connect the parameters of the bulk lattice to those (not shown) specific to the Zn vacancy. The solid curves are obtained from the fitting of the temperature-dependent trapping model [46.35]

Fig. 46.11 Average positron lifetimes and the second lifetime components extracted from the lifetime spectra measured in HNP and HVPE GaN samples. The solid curves represent the fits of the temperature-dependent trapping model. The solid lines in the upper and lower parts of the figure show the average values of τ_{ave} and τ_2 in regions of no temperature dependence [46.45]

traps. Negative ions are able to bind positrons at shallow (< 0.1 eV) hydrogenic states in their attractive Coulomb field (Sect. 46.1). Since they possess no open volume, the lifetime of positrons trapped at them is the same

as in the defect-free lattice, $\tau_{\text{ion}} = \tau_{\text{B}} = 160 \pm 1$ ps. The average lifetime increases above 150 K when positrons start to escape from the ions and a larger fraction of them annihilates at vacancies.

The temperature dependence of the average lifetime can be modeled with the kinetic trapping equations introduced in Sect. 46.1. The positron trapping coefficients at negative Ga vacancies μ_{V} and negative ions μ_{ion} vary as $T^{-1/2}$ as a function of temperature [46.3,8]. The positron escape rate from the ions can be expressed as $\delta(T) \propto \mu_{\text{ion}} T^{-3/2} \exp(-E_{\text{ion}}/k_{\text{B}}T)$, where E_{ion} is the positron binding energy at the Rydberg state of the ions (46.10). The fractions of annihilations at Ga vacancies η_{V} and at negative ions η_{ion} are given in (46.16–46.17) and they depend on the concentrations $c_{\text{V}} = \kappa_{\text{V}}/\mu_{\text{V}}$ and $c_{\text{ion}} = \kappa_{\text{ion}}/\mu_{\text{ion}}$ of Ga vacancies and negative ions (46.9), respectively, as well as on the detrapping rate $\delta_{\text{ion}}(T)$ (46.10). We take the conventional value $\mu_{\text{V}} = 2 \times 10^{15} \text{ s}^{-1}$ for the positron trapping coefficient at 300 K [46.8, 9]. Inserting the annihilation fractions η_{B} , η_{ion} , and η_{V} from (46.15–46.17) into the equation for the average lifetime $\tau_{\text{ave}} = \eta_{\text{B}}\tau_{\text{B}} + \eta_{\text{ion}}\tau_{\text{ion}} + \eta_{\text{V}}\tau_{\text{V}}$ (46.18), the resulting formula can be fitted to the experimental data of Fig. 46.11 with c_{V} , c_{ion} , μ_{ion} , and E_{ion} as adjustable parameters. As indicated by the solid lines in Fig. 46.11, the fits reproduce well the experimental data with the positron binding energy of $E_{\text{ion}} = 60 \pm 10$ meV and trapping coefficient $\mu_{\text{ion}} = (7 \pm 4) \times 10^{16} (T/\text{K})^{-0.5}$. These values are close to those obtained previously in, e.g., GaAs and GaN [46.8,28,46].

Even though the negative ions cannot be identified based on the positron data alone, their concentrations can be determined and compared with acceptor impurity concentrations measured with SIMS. In as-grown GaN samples, the negative ion concentrations obtained from positron experiments correlate with the concentrations of magnesium (Mg) impurities in both HVPE- and HNP-grown samples [46.45,46]. This indicates that, as expected, the Mg impurities act as compensating defects in n-type GaN.

46.3 Defects, Doping, and Electrical Compensation

The concentrations of the defects detected by positrons can be estimated from their respective annihilation fractions. This can be done in a straightforward manner even when the exact defect structure such as the decoration by impurities of a vacancy remains unre-

solved. The experimental annihilation fractions depend on the trapping rates to the different defects through (46.16–46.17), and the trapping rate κ_{D} to a specific defect is directly proportional to the defect concentration c_{D} (46.9). The proportionality constant is called

the trapping coefficient μ_D (Sect. 46.1). The values and behavior as a function of temperature of the trapping coefficients depend on the type and charge state of the defect, and have been estimated both experimentally and by theoretical calculations [46.25–27]. Even though the absolute magnitude of the trapping coefficient may be off by a factor of two or three from the physically proper value, differences in vacancy concentrations in a given material can be detected with the high accuracy of the lifetime experiment: changes as low as 1 ps can be reliably detected in the average positron lifetime of about 200 ps. In this section studies of vacancy–donor complexes in Si and GaN are presented.

46.3.1 Formation of Vacancy–Donor Complexes in Highly n-Type Si

Doping levels up to 10^{20} cm^{-3} are used in current device technologies. In n-type doping of Si with arsenic, however, fundamental material problems start to appear when the impurity concentration increases above $\approx 3 \times 10^{20} \text{ cm}^{-3}$ [46.50, 51]. The concentration

of the free carriers (electrons) does not increase linearly with the doping concentration, indicating that inactive impurity clusters or compensating defects are formed. Furthermore, the diffusion coefficient of As starts to increase rapidly at $[\text{As}] > 3 \times 10^{20} \text{ cm}^{-3}$, demonstrating that new migration mechanisms become dominant [46.52].

Both the electrical deactivation of dopants and the enhanced As diffusion have often been attributed to the formation of vacancy–impurity complexes [46.51]. According to theoretical calculations, vacancies surrounded by several As atoms (V-As_n , $n > 2$) have negative formation energies, suggesting that these complexes are abundantly present at any doping level [46.53, 54]. The formation of these defects is however limited by kinetic processes such as the migration of As. The calculations predict that also the V-As_2 complex is mobile at relatively low temperatures, enabling the formation of higher-order V-As_n complexes [46.54, 55]. As shown in Sect. 46.2, the dominant structure of vacancy complexes has been identified as V-As_3 in Czochralski (CZ) Si doped up to $[\text{As}] = 10^{20} \text{ cm}^{-3}$ [46.43, 56].

In order to verify the formation mechanism of the V-As_3 complexes in highly As-doped Si, electron-irradiated Si ($[\text{As}] = 10^{20} \text{ cm}^{-3}$) samples, where V–As pairs were observed as dominant vacancy complexes defects, were subjected to thermal annealing experiments. Figure 46.12 shows the behavior of the average positron lifetime measured at room temperature as a function of the annealing temperature [46.49, 57]. For comparison, data obtained in P-doped Si ($[\text{P}] = 10^{20} \text{ cm}^{-3}$) samples subjected to similar irradiation and annealing are also shown in the figure. In Si ($[\text{As}] = 10^{20} \text{ cm}^{-3}$) the lifetime is around 242 ps up to 1100 K, indicating the presence of monovacancies. The peak at 500 K is due to the formation and annealing of divacancy defects [46.49, 57]. In the P-doped sample the average lifetime is initially higher due to a slightly higher concentration of divacancies, and decreases dramatically already after the annealing at 700 K, indicating that the vacancy concentration decreases at a lower temperature than in As-doped Si.

Coincidence Doppler broadening measurements were performed simultaneously with the lifetime experiments. As explained in Sect. 46.2.1, the vacancy defects observed after irradiation in As-doped Si are the V–As pairs (Fig. 46.7). After annealing at 600 K, the intensity of the high-momentum part (2–4 a.u.) has increased, and the defect in question can be identified as the V-As_2 complex by comparison with theoretical cal-

Fig. 46.12 Average positron lifetime measured at room temperature as a function of annealing temperature for the electron-irradiated Si samples. The annealings were performed isochronally (30 min at each temperature) in vacuum [46.49]. The regions where each of the vacancy–donor complex (V-D_n) is the dominant defect are also shown

culations. After annealing at 775 K, the intensity of the high-momentum part further increases up to the level of the V-As₃ complex (Fig. 46.7). The measurement after annealing at 1000 K gives the same Doppler-broadened spectrum, indicating that the defects are still the V-As₃ complexes formed around 700 K. After 1100 K the average lifetime (Fig. 46.12) starts to decrease, indicating that the vacancy defects are annealing away.

The average lifetime data in Fig. 46.12 suggests that similar dissociation and complexing of vacancy-donor pairs occurs in P-doped Si as well. It is worth noticing that the divacancy-related peak in the average lifetime is at a slightly lower temperature and the peak is slightly higher, demonstrating the fact that the V-P pairs formed in the irradiation are a slightly less stable than the V-As pairs. This, together with the initially higher average lifetime, shows that the formation of V₂ is more efficient in P-doped Si. In both the As- and P-doped samples no divacancies are observed (based on the separation of the lifetime components) after the annealing at 600 K. In P-doped Si, the high momentum part of the Doppler-broadened spectrum cannot be used in the identification of the complexes with different numbers of P atoms due to the similarity of the core electron distributions of P and Si (Sect. 46.2.1). On the other hand, the distribution in the valence region (momentum values below 0.5 a.u.) after the 600 K annealing is clearly broader than in the as-irradiated sample. This effect is observed in the case of As doping as well and is reproduced by theory. The broadening indicates the increased presence of positive P ions next to the vacancy causing increased valence electron density, leading to increased electron momentum. The valence region broadens further after 775 K annealing. Hence a similar conversion of V-P to V-P₂ and finally V-P₃ is observed in P-doped Si as for the V-As_n complexes in As-doped Si. However, the dissociations seem to be more dominant in P-doped Si, since only a small fraction of the V-P pairs are finally converted to V-P₃ by annealing. The difference may be related to the lower binding energy of the P-decorated vacancy complex as manifested by the lower annealing temperature of the V-P pairs compared with that of the V-As pairs [46.57].

In addition to particle irradiation, vacancies are formed in thermal equilibrium at relevant concentrations in highly doped Si when the sample temperature exceeds 650 K [46.58,59]. The vacancies are formed directly next to the dopant atoms, which reduces the high formation energy of the isolated vacancy of about 3 eV in highly n-type Si by the Coulomb binding energy and the ionization energy down to about 1 eV [46.58]. The

vacancy-donor pairs diffuse rapidly at these temperatures and finally form complexes with three donor atoms either already at the annealing temperature or during cooling down. These results have been obtained by both isochronal and isothermal annealing experiments, and positron measurements both at room temperature in between the annealings and in situ during the annealings. An interesting feature is that the detection of V-As₃ complexes at high temperatures is difficult due to positrons escaping from them above 500 K, indicating that the binding energy is about 0.25 eV [46.59], significantly lower than that typically observed (at least about 1 eV) for vacancy defects in semiconductors, as for example, in V-P₃.

The vacancy concentrations can be estimated in a straightforward manner when the vacancy-specific and bulk annihilation parameters are known. Equation (46.25) provides the relationship between the trapping rate and the experimental parameters. The vacancy concentration is proportional to the trapping coefficient, and can be obtained, e.g., from the Doppler data as

$$[V] = \frac{N_{\text{at}}}{\mu_V \tau_b} \frac{W - W_B}{W_V - W}, \quad (46.29)$$

where N_{at} is the atomic density. In the following, we have used the positron trapping coefficient $\mu_V = 10^{15} \text{ s}^{-1}$ for the Si vacancies and $\tau_b = 218 \text{ ps}$ for the positron lifetime in defect-free Si.

The concentration of the V-As₃ complexes in Czochralski-grown Si ([As] = 10^{20} cm^{-3}) is only 0.1% of the As concentration [46.43], and the material does not show substantial electrical deactivation. In addition, molecular-beam epitaxy (MBE) can be applied to achieve metastable n-type doping with Sb that becomes compensated only at 10^{21} cm^{-3} [46.60]. In order to illustrate the importance of vacancy defects in the compensation, selected electrical and positron results obtained with a slow positron beam in MBE-grown Si thin layers with [As] > 10^{20} cm^{-3} and [Sb] = 2.7×10^{19} – $3.7 \times 10^{21} \text{ cm}^{-3}$ [46.61, 62] are shown in Table 46.1. Here only the Doppler broadening spectra have been measured and the identification of the vacancy-donor complexes is based on the characteristic data acquired in the experiments on the electron-irradiated samples presented above.

The results show that the as-grown As-doped MBE Si layers are efficiently compensated, but the doping can be activated through rapid thermal annealing (RTA), a routinely used technique in device processing for this purpose. The total vacancy concentrations in these sam-

Table 46.1 Donor concentrations and electrical activities of highly As- and Sb-doped MBE Si samples. The total vacancy concentrations have been determined by combining electrical and positron experiments [46.61, 62]

Donor concentration (cm ⁻³)	Description	Electrical activity (%)	Total [V] (cm ⁻³)
[As] = 1.5 × 10 ²⁰	As-grown (720 K)	20	4 × 10 ¹⁹
[As] = 1.5 × 10 ²⁰	RTA 1170 K	98	1 × 10 ¹⁸
[As] = 3.5 × 10 ²⁰	As-grown (720 K)	2	1 × 10 ²⁰
[As] = 3.5 × 10 ²⁰	RTA 1170 K	85	1.5 × 10 ¹⁹
[Sb] = 2.7 × 10 ¹⁹	As-grown (550 K)	90	≤ 10 ¹⁹
[Sb] = 5.9 × 10 ²⁰	As-grown (550 K)	70	5 × 10 ¹⁹
[Sb] = 9.4 × 10 ²⁰	As-grown (550 K)	70	1.5 × 10 ²⁰
[Sb] = 3.7 × 10 ²¹	As-grown (550 K)	6	9 × 10 ²⁰

ples, which are high enough to be dominant in the compensation, are dramatically reduced in the RTA treatments. The vacancies in question are dominantly the V–As₃ complexes, but also more complicated defect structures such as V₂–As₅ give a nonvanishing contribution [46.61].

The highly Sb-doped MBE Si layers grown at low temperature, where the V–Sb₂ complex is stable [46.57], contain defects such as V–Sb₂ and V₂–Sb₂ instead of V–Sb₃ [46.62]. It is clearly seen from the total vacancy concentrations that they play an important role in the compensation of the Sb-doped layers as well. However, the electrical activity of the as-grown samples is far better than those grown at higher temperatures (and doped with As). This can be explained by the migration processes described above, i.e., the V–Sb₂ do not diffuse and form V–Sb₃ complexes, enabling a larger fraction of the dopants to be isolated and active.

46.3.2 Vacancies as Dominant Compensating Centers in n-Type GaN

Gallium nitride (GaN) is an important wide-band-gap semiconductor for optoelectronic and electronic applications. It can be grown by several methods, each of which have partially different impurity and defect characteristics. The oxygen and silicon impurities dope GaN to an n-type semiconductor. The conductivity of n-type GaN is partly compensated by Ga vacancies [46.46]. It is now possible to perform more exact and quantitative studies of defects in GaN due to the improved quality of the material over the past few years. In particular, GaN grown by hydride vapor-phase epitaxy (HVPE) has low residual impurity (10¹⁶ cm⁻³) and dislocation (< 10⁸ cm⁻²) densities. In such a material, the relation between intentional doping and compensating defects can be systematically studied.

The average positron lifetimes measured in free-standing HVPE GaN samples with different levels of intentional doping with oxygen are shown as a function of measurement temperature in Fig. 46.13 [46.44, 63]. Also data from an earlier study of nominally undoped but contaminated by O (concentration in the 10¹⁷ cm⁻³ range) 40 μm thick HVPE GaN on sapphire is shown for comparison [46.47]. The average lifetime is higher than in the defect-free GaN lattice (τ_B = 160 ps) in all the samples, indicating that positrons are trapped at vacancy defects. The vacancy defect present is related to V_{Ga}, since the decomposition reveals the component

Fig. 46.13 Average positron lifetime as a function of measurement temperature in intentionally oxygen-doped free-standing HVPE GaN samples and one nominally undoped 40 μm thick HVPE GaN/Al₂O₃ sample

$\tau_2 = 235 \pm 5$ ps. There is a clear increasing trend of the average lifetime with the oxygen and free electron densities, indicating that the Ga vacancy concentration follows that of oxygen.

The increase of the average positron lifetime with decreasing temperature shows that the positron trapping rate increases at low temperatures. The temperature dependence of the average positron lifetime is totally reversible and reproducible, indicating that the concentration of Ga vacancies remains constant. Because the Fermi level is close to the conduction band, the charge states of acceptor-like defects such as V_{Ga} do not change with the measurement temperature. Hence, as explained in Sect. 46.1, this effect is a direct indication that the Ga vacancies are in the negative charge state. This is in excellent agreement with the results of theoretical calculations [46.64] that predict a charge state of 3− for the isolated Ga vacancy and 2− for $V_{\text{Ga}}\text{--O}_{\text{N}}$ and $V_{\text{Ga}}\text{--Si}_{\text{Ga}}$ complexes in n-type GaN.

The positron data show further that the defects involving Ga vacancies are the *dominant* negatively charged acceptors in the samples. The enhancement of positron trapping at low temperatures would not be observed if other negative centers competed with V_{Ga} as positron traps. For example, negative ions such as Mg_{Ga}^+ localize positrons at hydrogenic states at low temperatures, strongly decreasing the fraction of positron annihilations at vacancy defects and consequently the average positron lifetime (Sect. 46.2.3). The same behavior could be expected for possible neutral or negative charge states of the N vacancy, where the positron lifetime is very close to that of the GaN lattice.

The Ga vacancy concentrations in the GaN samples can be estimated from the positron results using (46.25). They range from $4 \times 10^{15} \text{ cm}^{-3}$ in the lowest-doped ($[\text{O}] = 2 \times 10^{17} \text{ cm}^{-3}$) to about 10^{17} cm^{-3} in the highest-doped sample ($[\text{O}] = 2 \times 10^{20} \text{ cm}^{-3}$), in correlation with the O concentration. According to electron irradiation studies, the isolated V_{Ga} is mobile already at 600 K [46.65], i. e., at much lower temperatures than applied in the HVPE growth. However, the Ga vacancies bound to defect complexes such as $V_{\text{Ga}}\text{--O}_{\text{N}}$ have a considerably higher thermal stability [46.45,65,66]. In

fact, recent detailed studies of the electron momentum density show that the dominant vacancy defect, responsible for the positron lifetime of 235 ps, is a complex of Ga vacancy and oxygen [46.44].

Unlike in the case of vacancy–donor pairs in highly n-type silicon (see previous section), the Ga vacancies are formed as isolated during growth of n-type GaN. They migrate fast at the high growth temperatures that are typically above 1300 K in the case of bulk or quasibulk crystals, and are stabilized (quenched) by donor impurities during cooling down. This is demonstrated by the fact that the $V_{\text{Ga}}\text{--O}_{\text{N}}$ concentrations are similar in materials grown by HVPE and the high-nitrogen-pressure method when the O concentrations are similar, in spite of the large difference of about 500 K in the growth temperatures [46.45]. In fact, it has been shown that the $V_{\text{Ga}}\text{--O}_{\text{N}}$ pairs are stable up to about 1300 K [46.66]. On the other hand, the concentration of Ga vacancies in Si-doped n-type GaN is significantly lower than in O-doped n-type GaN with similar free electron concentration due to the lower binding energy of the $V_{\text{Ga}}\text{--Si}_{\text{Ga}}$ pair originating from the larger distance between the individual acceptor (Ga vacancy) and donor (substitutional Si) defects [46.67].

The positron results show that Ga vacancies act as dominant compensating centers in n-type GaN. On the other hand, in p-type GaN, where the formation of Ga vacancies is energetically unfavorable due their acceptor nature, the natural question is whether N vacancies could compensate the doping. The detection of vacancy defects on the N sublattice with positrons is not evident due to the small open volume generated by the missing N atom. Nevertheless evidence of the existence N vacancies complexed with Mg ($V_{\text{N}}\text{--Mg}_{\text{Ga}}$) has been obtained with positrons in Mg-doped (p-type) GaN grown by metalorganic chemical vapor deposition (MOCVD) [46.68,69]. It is worth noting that, even though the vacancy concentrations are similar relative to the doping densities (a few percent at most) in both n- and p-type GaN, the vacancies are dominant compensating centers only in n-type GaN, while in p-type GaN other defects and impurities such as hydrogen play the most important role.

46.4 Point Defects and Growth Conditions

Compound semiconductor thin films can be epitaxially grown by several methods such as metalorganic chemical vapor deposition (MOCVD) or molecular-beam

epitaxy (MBE). There are many controllable growth parameters that affect the properties of the overgrown layers, such as the growth rate, stoichiometry, and tem-

perature. In addition, the layer properties may depend on the choice of the substrate material and the orientation of the substrate or the layer. Especially in the case of heteroepitaxy, the layer properties may vary significantly with the distance from the layer/substrate interface. The identities and quantities of both extended and point defects are affected by these parameters. In this section we will also describe how point defects can be studied in thin semiconductor layers by using a variable-energy positron beam.

46.4.1 Growth Stoichiometry: GaN Versus InN

The effect of the growth stoichiometry on the formation of cation vacancies in GaN and InN has been studied by measuring a set of samples grown by MOCVD employing different V/III molar ratios [46.70, 71]. The growth rate as well as the electrical and optical properties of the nitride samples change strongly with the V/III molar ratio [46.72, 73]. All the samples were investigated at room temperature as a function of the positron beam energy E . When positrons are implanted close to the sample surface with $E = 0$ –1 keV, the same S parameter of $S = 0.49$ is recorded in all the GaN and InN samples. These values characterize the defects

and chemical nature of the near-surface region of the samples at the depth 0–5 nm. S parameter data from selected GaN and InN samples are shown as a function of positron implantation energy in Fig. 46.14. In the GaN samples the S parameter is constant at 5–15 keV, indicating that all positrons annihilate in the GaN layer (Fig. 46.14), while in the InN samples the region of constant S is different from sample to sample due to the different thicknesses of the layers. The data recorded at the energies where S is constant can be taken as characteristic of the layer. In the case of GaN, the lowest S parameter is obtained in the Mg-doped reference layer [46.46], while for InN the reference value was obtained from a several microns thick layer grown by MBE [46.74]. The values in these samples correspond to positrons annihilating as delocalized particles in the defect-free lattice.

The S parameters in all the measured layers are larger than in the reference samples, as in Fig. 46.14. The increased S parameter indicates that the positron–electron momentum distribution is narrower than in the defect-free reference sample. The narrowing is due to positrons annihilating at vacancy defects, where the electron density is lower and the probability of annihilation with high-momentum core electrons is reduced compared with that of delocalized positrons in the lattice (Sect. 46.1). The increased S parameter is thus a clear sign of vacancy defects present in the measured layers.

The number of different vacancy defects trapping positrons can be investigated through the linearity between the low- and high-electron-momentum parameters S and W . If only a single type of vacancy is present, the W parameter depends linearly on the S parameter when the fraction of positron annihilations at vacancies η_V varies. The plot of the W parameter versus S parameter thus forms a line between the endpoints (S_B , W_B) and (S_V , W_V) corresponding to the defect-free lattice and the total positron trapping at vacancies, respectively. The S and W parameters of all the GaN and InN samples are plotted in Fig. 46.15. All the data points measured in GaN fall on the line connecting the parameters obtained in the Mg-doped GaN reference sample and those determined in earlier studies for the native Ga vacancy [46.46]. Hence Ga vacancies are found in all the GaN samples. Similarly the data points measured in the InN samples fall on the line connecting the parameters of the defect-free InN lattice and those of the In vacancy, also determined in an earlier study [46.74], indicating the presence of In vacancies in these samples. In GaN, the positron trapping fraction η_V and the

Fig. 46.14 The low-electron-momentum parameter S as a function of the positron implantation energy in three GaN and three InN samples. The *top axis* shows the mean stopping depth corresponding to the positron implantation energy

S parameter vary from one sample to another due to the different vacancy concentrations, while in InN the data indicates that the In vacancy concentrations are similar in all the samples. It is worth noticing that the data recorded in the InN samples are shifted with respect to that measured in the GaN samples by the differences in the parameter levels in the two materials: the S parameter is higher and W lower in defect-free InN than in defect-free GaN due to the differences in the electronic structures.

The presence of Ga vacancies is expected in n-type undoped GaN due to their low formation energy. The different levels of the S parameter in Figs. 46.14 and 46.15 indicate that the concentration of the Ga vacancies depends on the stoichiometry of growth. On the other hand, in InN the data are similar for all the samples with different V/III ratios, indicating that the In vacancy concentration is independent of the growth stoichiometry.

In order to quantify the concentration of V_{Ga} and V_{In} the S parameter data was analyzed with the positron trapping model. When the cation vacancies are the only defects trapping positrons, their concentration can be determined with the simple formula (46.25)

$$[V_{\text{Ga/In}}] = \frac{N_{\text{at}}}{\mu_V \tau_b} \frac{S - S_B}{S_V - S} \quad (46.30)$$

where $\tau_b = 160$ ps (185 ps) is the positron lifetime in the GaN (InN) lattice [46.46, 74], $\mu_V = 3 \times 10^{15} \text{ s}^{-1}$ is the positron trapping coefficient [46.8], and $N_{\text{at}} = 8.775 \times 10^{22} \text{ cm}^{-3}$ ($6.367 \times 10^{22} \text{ cm}^{-3}$) is the atomic density of GaN (InN). For the S parameter at the Ga and In vacancies we take $S_V/S_B = 1.050$ [46.46, 70, 71, 74].

The results in Fig. 46.16 indicate that the concentration of Ga vacancies in GaN is proportional to the stoichiometry of the growth conditions. Rather low $[V_{\text{Ga}}] \approx 10^{16} \text{ cm}^{-3}$ is observed for the sample with the V/III molar ratio of 1000. When the V/III molar ratio becomes 10 000, the V_{Ga} concentration increases by almost three orders of magnitude to $[V_{\text{Ga}}] \approx 10^{19} \text{ cm}^{-3}$. This behavior shows that empty Ga lattice sites are likely formed in the strongly N-rich environment. In contrast, the concentration of In vacancies in InN remains constant at the level of $[V_{\text{In}}] \approx 10^{17} \text{ cm}^{-3}$ over the whole range of V/III molar ratios from about 3000 to 24 000. The In vacancy concentration in these samples is on the same level as in samples of similar thickness grown by MBE where the growth conditions are much closer to being stoichiometric, suggesting that the In vacancy formation is dominated by thickness-dependent properties such as strain or dislocation

Fig. 46.15 The low- and high-momentum parameters S and W in various GaN and InN samples. The V/III molar ratio of each sample is indicated in the figure. The straight line indicates that the same vacancy defect (group III vacancy) is observed in all samples. Note the different scales on the left/right and top/bottom axes

Fig. 46.16 The concentrations of Ga and In vacancies versus the V/III molar ratio in GaN and InN samples grown by MOCVD. The straight lines are drawn to emphasize the correlations [46.70, 71]

density. In fact, in MBE-grown InN, the In vacancy concentration drops by several orders of magnitude when the layer thickness increases from a few hundred nanometers to a few microns [46.74].

The difference in the behavior of the cation vacancies in GaN and InN as a function of the V/III molar ratio can be explained by the differences in the calculated vacancy formation energies and the temperatures of the MOCVD growth. In n-type material the calculated formation energy of the Ga vacancy is about 1.3 eV, while it is about 2.6 eV in InN [46.64, 75]. On the other hand, the growth temperature of the GaN samples was around 1000 °C, but only 550 °C in the case of InN samples [46.70, 71]. As the concentrations of the Ga and In vacancies are similar in the samples with low V/III ratios, the formation of the In vacancies must be dictated by other effects, such as strain or presence of dislocation, than the thermal formation (and subsequent stabilization by, e.g., impurities) of an isolated In vacancy in an otherwise perfect lattice. On the other hand, the observed Ga vacancy concentrations are of the same order of magnitude that could be expected from the growth temperature and the calculated formation energy, given that the vacancies (which are mobile already at relatively low temperatures) are stabilized by, e.g., O impurities close to the growth temperature. Hence it is understandable that the stoichiometric conditions affect the final Ga vacancy concentration in GaN more than the In vacancy concentration does in InN.

46.4.2 GaN: Effects of Growth Polarity

The wurtzite structure of GaN introduces effects related to the growth polarity of the layer. In the following, studies of both polar (Ga or N polarity) and nonpolar layers are reviewed [46.45, 47, 76]. The positron lifetime was measured in GaN layers grown by hydride vapor-phase epitaxy (HVPE) on dislocation-free high-pressure (HNP) bulk GaN crystals to thicknesses 30–160 μm [46.45]. Four of the layers were grown on the Ga face and one layer on the N face of the HNP GaN substrate. One of the Ga polar layers (30 μm) was grown in the same run with the N polar layer. Apart from the thickness, the properties of the Ga polar layers were similar to each other.

The average positron lifetimes measured as a function of temperature in the HVPE and HNP GaN samples are shown in Fig. 46.11. As shown in the figure, a second lifetime component of $\tau_2 = 235 \pm 10$ ps could be separated in the lifetime spectra, indicating that positrons annihilate as trapped at Ga vacancy related

defects when the average positron lifetime is above the bulk lifetime of 160 ps. On the other hand the decrease of the average positron lifetime with decreasing temperature in the samples (HNP GaN and N-polar HVPE GaN), where τ_{ave} is above τ_B , is a clear indication of the presence of negative ion defects trapping positrons at low temperature to hydrogenic states, where the positron lifetime is equal to τ_B .

Interestingly, the Ga vacancy concentrations ($7 \times 10^{17} \text{ cm}^{-3}$) coincide in the N-polar HVPE GaN and the N side of the HNP GaN samples, similarly as the impurity concentrations obtained from secondary-ion mass spectrometry (SIMS) experiments. On the other hand, the difference between the Ga-polar HVPE GaN ($[\text{V}_{\text{Ga}}] < 10^{16} \text{ cm}^{-3}$) and the Ga side of the HNP GaN bulk crystal ($[\text{V}_{\text{Ga}}] = 2 \times 10^{17} \text{ cm}^{-3}$) is significant. These observations support the idea proposed earlier [46.77], namely that the oxygen incorporation (and subsequent Ga vacancy formation) is stronger in the nonpolar directions, in which the N-polar growth mainly proceeds. The difference between the polarities is larger in the HVPE GaN samples than in the HNP bulk GaN crystals. This can be explained by the lower temperature and pressure in HVPE growth, which reduce the oxygen diffusion, and by the presence of more oxygen in the high-pressure growth.

In order to further study the role of growth polarity on the defect incorporation in GaN, *a*-plane GaN layers (thicknesses 1–25 μm) grown on sapphire were measured with a variable-energy positron beam [46.76]. The *S* parameter measured in these layers is shown as a function of positron implantation energy in Fig. 46.17. Ga vacancies complexed with oxygen were identified in the layers, and their concentrations are shown as a function of distance from the interface in Fig. 46.18. For comparison, also the data from the *c*-plane GaN [46.47] are reproduced here. The difference between the polar and nonpolar HVPE GaN layers is clear: the Ga vacancy concentration is constant in the *a*-plane HVPE GaN, whereas it decreases with increasing distance in *c*-plane HVPE GaN. SIMS results show that the O concentration is also constant in the HVPE GaN layers, as is the density of extended defects (observed with cross-sectional transmission electron microscopy).

These results give further support for the model based on growth-surface-dependent oxygen incorporation and subsequent Ga vacancy formation. In *c*-plane heteroepitaxial Ga-polar HVPE GaN, the O concentration profile is determined by the dislocation profile likely due to diffusion from the sapphire substrate. On the other hand, in homoepitaxial *c*-plane Ga-polar

HVPE GaN, in which the dislocation density is low and the amount of oxygen in the substrate is significantly lower, no vacancies are observed even in the thinnest layers, while in N-polar GaN both the Ga vacancy and O concentrations are high. Hence, as the growth modes are similar in the N-polar and nonpolar GaN, it is natural that the O incorporation from the growth ambient is effective in both, giving rise to a high O concentration and subsequent Ga vacancy concentration, independently of possible extended defects.

46.4.3 Bulk Growth of ZnO

Bulk ZnO crystals can be grown by various methods. In the following, we will compare the positron results [46.21] obtained in ZnO grown by the seeded vapor-phase (VP) [46.78], skull-melt [46.79], hydrothermal (HT) [46.80], and conventional and contactless chemical vapor transport techniques (CVT and CCVT) [46.81, 82]. The VP, skull-melt, CVT, and CCVT materials are all characterized by low (below 10^{17} cm^{-3}) impurity concentrations. In HT ZnO the concentration of the most abundant impurity, lithium, is in the 10^{18} cm^{-3} range in these samples. This is a general property of hydrothermally grown ZnO. All the studied samples were nominally undoped. ZnO grown by the HT method had high resistivity, likely due to Li, while the other materials were all slightly n-type due to residual impurities and/or intrinsic defects.

The average positron lifetimes measured as a function of temperature in all the different bulk ZnO crystals are collected in Fig. 46.19. As seen in the figure, the samples can be roughly divided into two groups, where in one the average lifetime τ_{ave} is very close to the bulk lifetime of $\tau_B = 170 \text{ ps}$ and in the other it is clearly above τ_B , in the 175–185 ps range. The ZnO crystals grown by the VP and skull-melt methods belong to the former and the crystals grown by the HT, CVT, and CCVT methods belong to the latter. As shown in the figure, a second lifetime component of $\tau_2 = 230 \pm 10 \text{ ps}$ (the same in all the samples) could be separated in the lifetime spectra, indicating that positrons annihilate as trapped at Zn vacancy related defects when the average positron lifetime is well above the bulk lifetime of 170 ps.

The ZnO crystals grown by the VP technique were obtained from Eagle-Picher (EP) and ZN-Technologies (ZNT), and the crystals grown by the skull-melt technique from Cermet. As explained in Sect. 46.2.2, the EP material contains Zn vacancies in the double-negative charge state, evident from the separation of

Fig. 46.17 The S parameter in the a -plane GaN layers as a function of positron implantation energy. The solid and dashed lines show the S parameter in the GaN lattice and at a Ga vacancy, respectively. Also the S parameters measured in the GaN reference and in the sapphire substrate are shown [46.21]

the lifetime components and the increase of the average lifetime with decreasing temperature. The average

Fig. 46.18 Estimated Ga vacancy concentrations as a function of the distance from the sapphire interface [46.21, 47]

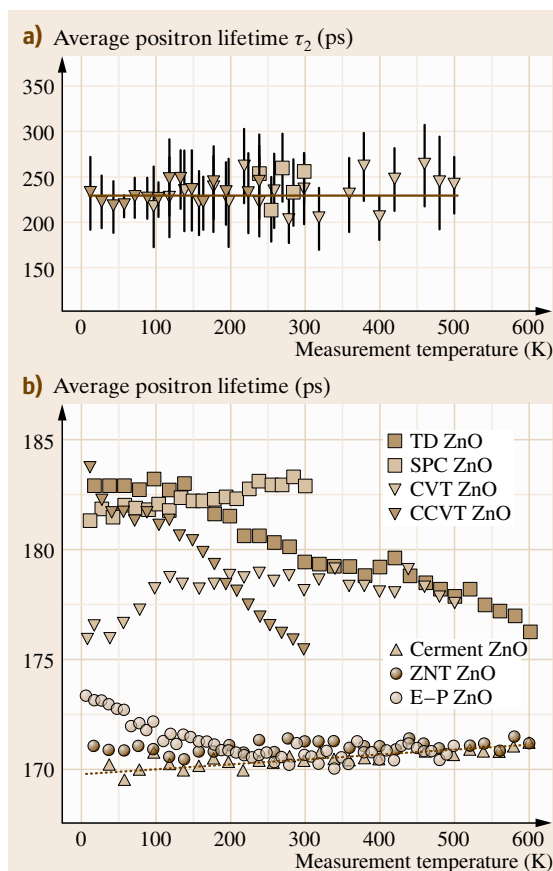

Fig. 46.19a,b The average positron lifetime (a) and the higher lifetime components separated from the annihilation spectra (b) as a function of measurement temperature in all the measured ZnO samples

lifetime of 173 ps at 20 K corresponds to a concentration of $[V_{\text{Zn}}] = 2 \times 10^{15} \text{ cm}^{-3}$. The positron lifetime representative of the pure ZnO lattice was fitted to the data obtained above 300 K, and is shown as the dotted line in Fig. 46.19. The slight increase with increasing temperature is due to the thermal expansion of the lattice. The ZNT ZnO is nominally identical to EP ZnO, and the average positron lifetimes in these two materials coincide above 300 K, but at lower temperatures the average lifetime is lower in the ZNT ZnO (about 171 ps at 20 K compared with 173 ps in EP ZnO), but still slightly above the fitted ZnO lattice lifetime. This indicates that a very small but measurable fraction of positrons annihilates at vacancy defects (concentration lower than in EP ZnO, about 10^{15} cm^{-3}), which are presumably Zn vacancies. However, the fraction is too

small for the lifetimes to be separable from the lifetime spectrum and hence the defects cannot be conclusively identified. Interestingly, the average positron lifetime measured in Cermet ZnO coincides with the lifetime of the ZnO lattice estimated from the EP ZnO data over the whole temperature range of the measurements, and no higher components could be separated from the lifetime spectra at any temperature. This indicates that the concentration of vacancy defects in this material is below the detection limit of positron annihilation spectroscopy, i. e., well below 10^{15} cm^{-3} .

The ZnO crystals grown by the HT method were obtained from Tokyo Denpa (TD) and the Scientific Production Company (SPC). The average positron lifetime is of similar magnitude (180–185 ps) in the TD and SPC ZnO crystals, about 10–15 ps above the lattice ZnO lifetime measured in the EP ZnO, in excellent agreement with earlier reports of positron lifetimes in ZnO crystals grown by the hydrothermal method [46.83, 84]. The main difference between the TD and SPC ZnO crystals is in the behavior of the average positron lifetime with measurement temperature: the average positron lifetime decreases with increasing temperature in TD ZnO, while it increases slightly in SPC ZnO. This indicates that positrons are trapped at negatively charged vacancy defects in TD ZnO, while the data in SPC ZnO suggest that the vacancy defects are neutral and that positrons are also trapped at negatively charged non-open volume defects (negative ions). The negatively charged vacancy defects in TD ZnO are likely to be Zn vacancies.

An average lifetime higher than that in the defect-free ZnO lattice indicates that a fraction of the annihilating positrons must be trapped at vacancy defects. An average lifetime value 10–15 ps different than that in the bulk is typically enough for the separation of lifetimes, as in, e.g., the case of electron-irradiated EP ZnO (Sect. 46.2.2). However, in these hydrothermal samples the separation was possible only in SPC ZnO at 250–300 K, indicating that Zn vacancies are present in the SPC ZnO as well. The problems in the separation of the lifetime components suggest that there is a relatively high intensity of some additional lifetime between the bulk and Zn vacancy lifetimes in the lifetime spectrum. Larger vacancy defects with higher lifetimes than those of the Zn vacancy are not present, as there would then be no problems in the separation. A natural cause for these problems would be the presence of a relatively high concentration of neutral O vacancies (whose specific positron lifetime is $\tau_{\text{VO}} = 195 \pm 15 \text{ ps}$). In order to create such problems in the separation of the lifetimes, the

concentration of these O vacancy related defects needs to be in the $[V_O] \cong 10^{17} \text{ cm}^{-3}$ range. On the other hand, the concentrations of the Zn-vacancy-related defects causing the increase of the average positron lifetime with decreasing temperature in TD ZnO and evident from the separation of the lifetime components in SPC ZnO must be in the low 10^{16} cm^{-3} range.

The ZnO samples grown by the CVT and CCVT methods were grown at the Institute of Physics of the Polish Academy of Sciences. The average lifetime is above the bulk lifetime $\tau_B = 170 \text{ ps}$ in both the CVT- and CCVT-grown samples throughout the whole temperature range, indicating the trapping of positrons at vacancy defects. The lifetime spectra measured in both materials could be separated into two components, of which the higher was the V_{Zn} -related lifetime $\tau_2 = 230 \pm 10 \text{ ps}$, as shown in Fig. 46.19. The increase of the average lifetime with decreasing temperature in CCVT ZnO is a clear indication that the Zn vacancies are in the negative charge state. On the other hand, the independence from temperature of the average positron lifetime in CVT-grown ZnO in the range 100–500 K indicates that the observed vacancies are in the neutral charge state. The decrease in the average lifetime below 100 K in the CVT ZnO sample and the flat region at 50–100 K in the CCVT ZnO sample are interpreted as positrons trapping at negative-ion-type defects, which have no open volume and hence produce the annihilation characteristics of the bulk lattice. This is observed only at low temperatures, since the negative-ion-type defects act as shallow traps for positrons, and the escape rate at elevated temperatures is faster than the annihilation rate. The effect of the negative-ion-type defects is small in the CCVT ZnO sample, and hence the Zn vacancies are the dominant negatively charged (acceptor-type) defect. The concentration of the negative Zn vacancies (or related complexes) in CCVT ZnO can be estimated as $[V_{\text{Zn}}] \cong 1.5 \times 10^{16} \text{ cm}^{-3}$. The concentration of the negative-ion-type defects can be estimated to be roughly one order of magnitude lower.

The first lifetime component τ_1 (not shown) is well below the bulk lifetime τ_B in CCVT-grown ZnO, indicating that the one-defect trapping model works. However, in CVT-grown ZnO the first lifetime component coincides with τ_B , indicating the mixing of the bulk component with a defect-specific component with a lifetime close to (but higher than) the bulk lifetime [46.85]. This can be interpreted as positrons trapping at O vacancies. The concentrations of the neutral Zn-vacancy-related complexes in CVT-grown ZnO

can be estimated as $[V_{\text{Zn}}] \cong 2 \times 10^{16} \text{ cm}^{-3}$, and the negative ion concentration can be estimated to be of the same order of magnitude. The concentration of the O vacancies in CVT-grown ZnO can be estimated with trapping rate analysis as $[V_O] \cong 10^{17} \text{ cm}^{-3}$ [46.35, 85].

Interestingly, the Zn vacancy concentrations in the bulk ZnO crystals grown by the chemical vapor transport and hydrothermal methods are very similar, in spite of the growth environment being Zn-rich in the former and O-rich in the latter. Further, the presence of a rather high concentration of O-vacancy-related defects in the ZnO crystals grown by the hydrothermal method is surprising, and is likely to be connected to the high Li concentration in the material. In fact, the possibility that the defects interpreted as O vacancies could instead be some complicated complexes of Zn vacancies with Li and/or H (another light element that is quite abundant in ZnO) cannot be completely ruled out. On the other hand, the O-rich skull-melt and Zn-rich seeded vapor transport methods also produce ZnO crystals that are very much alike from the vacancy point of view. Hence it seems that, in the case of the bulk growth techniques, the formation of the vacancy defects is not greatly affected by the stoichiometry or the partial pressures of the growth environment, but rather by the residual impurities and other intrinsic defects.

An important observation to be made from Fig. 46.19 is that the higher lifetime component separated from the measured lifetime spectra (where it could be performed) is the same in all the samples over the whole measurement temperature range, i.e., $\tau_2 \cong 230 \text{ ps}$. It also coincides with that obtained in electron-irradiated material, hence demonstrating that the Zn vacancies are important defects in ZnO and supporting the determination of their lifetime value. In as-grown ZnO, it is very likely that the Zn vacancies are complexed with either residual impurities or other intrinsic defects, as the irradiation-induced (likely isolated) vacancies have been shown to anneal out from the material already at rather low temperatures of about 500–600 K [46.35]. This applies to the O vacancies as well.

The results obtained for the EP ZnO and CCVT ZnO show that the Zn vacancies act as dominant acceptors in n-type ZnO, similarly to the Ga vacancies in n-type GaN (see Sect. 46.3.2). The situation is more complicated in the ZnO crystals grown by the other techniques due to either too low a concentration of vacancies in general, or too high a concentration of other types of vacancies, such as O vacancies. The Zn vacancies are most likely complexed with donor-type defects, and as they survive

the cooling down from the high growth temperatures of about 1000 °C, the stabilizing donors are likely to be located on the O sublattice. In the case of cation vacancies complexed with cation-sublattice-substitutional donor defects, the binding energy is prone to be too low for the vacancies to be effectively stabilized, as in the case of Si donors in GaN [46.67]. As the total open volume of the in-grown Zn vacancies is the same as that of the irradiated Zn vacancies, it is likely that these donor defects are residual impurities, the concentrations

of which are of the same order of magnitude as that of the Zn vacancies. On the other hand, the possibility of the Zn vacancies being bound to O vacancies as $V_{\text{Zn}}-V_{\text{O}}$ complexes cannot be completely ruled out, as the latter are very difficult to distinguish from the isolated Zn vacancies with positrons. It is important, however, to understand that the O vacancies possibly observed in the hydrothermal- and CVT-grown bulk ZnO crystals are not complexed with the Zn vacancies, as the positrons are sensitive to the total open volume of the defect.

46.5 Summary

Positron annihilation spectroscopy gives microscopic information about vacancy defects in the concentration range 10^{15} – 10^{19} cm⁻³. The positron lifetime is the fingerprint of the open volume associated with a defect. It is used to identify mono- and divacancies and larger vacancy clusters. The Doppler broadening of the annihilation radiation measures the momentum distribution of the annihilating electrons. It can be used to identify the nature of the atoms surrounding the vacancy. Consequently, vacancies on different sublattices of a compound semiconductor can be distinguished, and impurities associated with the vacancies can be identified. The charge state of a vacancy defect is determined by the temperature dependence of the positron trapping coefficient. Positron localization into Rydberg states around negative centers yields information about ionic acceptors that have no open volume.

Positron methods can be applied to study vacancies in both bulk crystals and epitaxial layers. The mea-

surements in bulk crystals are straightforward, as (fast) positrons obtained directly from the radioactive source can be used. The studies of epitaxial layers and near-surface regions of bulk crystals require slow positrons. Typically in these cases a monoenergetic positron beam is used, the energy tuning of which allows for depth profiling of the samples in the range from a few nanometers to several microns.

Applications of the technique to Si, GaN, and ZnO have been presented. The Si vacancies complexed with donor impurities have been identified in highly n-type Si and their role as electrically compensating centers has been discussed. Ga vacancies complexed with oxygen are observed as native defects in n-type GaN, while N vacancies complexed with magnesium are detected in p-type GaN. The effects of growth conditions on the formation of group III vacancies have been discussed for GaN and InN. In ZnO, vacancies on both sublattices have been identified and their presence in bulk ZnO crystals grown by various methods is discussed.

47. Protein Crystal Growth Methods

Andrea E. Gutiérrez-Quezada, Roberto Arreguín-Espinosa, Abel Moreno

Nowadays, advances in genomics as well as in proteomics have produced thousands of new biological macromolecules for study in structural biology, biomedicine research, and drug design projects.

Novel and classical methods of protein crystallization as well as modern techniques for two-dimensional (2-D) and three-dimensional (3-D) characterization of different biomolecules are reviewed in this chapter. Production of high-quality single crystals will be analyzed in detail from classical approaches to modern, high-throughput crystal growth methods for x-ray diffraction, as will new strategies for reducing the amount of raw materials used, accelerating the work, and increasing success rates. It will be pointed out that this work on crystallization as well as characterization is multidisciplinary. These scientific efforts are also interrelated and require close collaboration between biochemists, biophysicists, microbiologists, and molecular biologists, as well as physicists and engineers to develop new strategies and equipment for structural purposes. Finally, some of the problems faced and plans for solving them by using x-ray diffraction, neutron diffraction, and electron microscopy will be revised.

Progress made in the biological sciences (biology, biochemistry, and biomedicine) during the last 25 years has been deeply dependent on the structural knowledge of atomic or molecular resolution of different types of biological macromolecules: proteins, nucleic acids (DNA more than RNA), and a small number of polysac-

charides. Much effort has been made worldwide to stimulate the structural study of proteins and of the different conformations they adopt in nature. The final aim is to understand the diversity of protein structural families, their folding, and the relation that exists between their composition and structure/function. Up to now, the

redundancy in the motifs and structural elements found in nature suggests that the number of different conformations is finite and manageable. Once most of them are known, it will be possible to predict the function of new, unknown protein domains. In this way, the modeling of these biological macromolecules will become one of the most promising tools for protein structure predictions in the near future.

On the other hand, structural biology has also famously influenced the field of protein engineering. While recombinant DNA techniques are used as synthetic tools, structure elucidation is used as an analytical tool. Advances in genomics have allowed the expression of proteins in live systems, the study of their activities, and based on their structure, their genetic modification for any practical purpose, such as increasing their stability or affinity for a substrate, inhibitor, etc. All this will revolutionize human life in different aspects: economics, health sciences, food sciences (nutrition), as well as in the development of new biomaterials with tailored properties based on the structure of biological systems.

Beyond the impact that structural biology has had on biochemistry, the three-dimensional structures of macromolecules have been demonstrated to be of formidable value in biotechnology. Nowadays, structural biology promotes the pharmacology field, through rational drug design based on the high-resolution structure of target macromolecules. This will have great impact on such diverse problems as curing human diseases, solving veterinary problems, and attacking crop damages [47.1].

Advances in genomics as well as in proteomics have produced thousands of new proteins for study in structural biology and drug design projects. The complete sequencing of vertebrate and invertebrate genomes [47.2] has accelerated international efforts to develop high-throughput methods and technologies that allow fast, three-dimensional protein structure determination [47.3]. Since the number of new proteins will continue to increase, as well as the number of scientists who study them, the necessity for new, efficient, and effective methods of structure determination has emerged [47.4]. Up to now, and in the near future, x-ray

diffraction of single crystals of specific macromolecules has been the only technique that can provide structural data at atomic resolution for these purposes. Other techniques that generate structural and molecular dynamic data do exist, but they are not used for the purposes expressed previously [47.1].

Some public and private projects have emerged under the names of structural genomics and structural proteomics. More recently, new terms have been created such as crystallomics, crystallogenesis, and chemotronics (a new branch between science and technology, related to the creation of liquid electrochemical converters in which ions in solution instead of electrons perform the role of current carriers). These efforts need fast and efficient techniques for three-dimensional structure elucidation. They are focused on high-throughput crystal growth for x-ray diffraction, considering new strategies for reducing the amount of raw material used, accelerating the work, and increasing success rates. These efforts are multidisciplinary and interrelated, and need close collaboration between biochemists, biophysicists, microbiologists, and molecular biologists, as well as physicists and engineers to develop new strategies and equipment. Herein, some of the problems faced and plans for solving them will be reviewed.

For x-ray crystallography to be applied to crystals of adequate size and quality, precise data collection is required. This converts crystals into the key to the whole process, and their production into the bottleneck. The problem of growing adequate crystals involves diverse aspects; in this chapter some of them will be commented on, such as model biomolecules, in addition to some novel and ingenious approaches to solving them, as well as their growth in a high-quality crystalline state.

One of the difficulties in obtaining high-quality crystals is the natural convection that exists in every experiment performed under normal Earth gravity conditions. In addition, problems involved in protein crystallization from solution, transport phenomena, and methods of crystal growth will be carefully reviewed. This is the reason why protein crystallization is so difficult: because of the lack of understanding of many of their physicochemical properties.

47.1 Properties of Biomacromolecular Solutions

Since all chemical reactions in biological systems take place in aqueous solutions, the question is: What is a so-

lution? By solution we understand a single phase, or a homogeneous system of variable composition formed

by at least two independent components. A homogeneous system is characterized by the absence of an interphase between the component parts of the solution, and by uniform composition and properties throughout the entire volume.

The components of a solution are the individual chemical substances which can be isolated from the system and which can exist in an isolated state. For example, an aqueous solution of lysozyme (model protein) consists of water (or buffer solution) and molecules of lysozyme. The solution components are the solute (protein) and the solvent (in general, water, for biological systems). The solute is the component of the solution in which the state of aggregation in normal conditions differs from that of the solution. The other components of the solution are known as solvents. In the case of liquid solutions, solutes are substances that under normal conditions are solid or gaseous, while the solvents are liquids.

The composition of a solution, in contrast to the composition of definite chemical compounds, can vary continually within wide limits. In this respect solutions are similar to chemical mixtures, though differing from them in their homogeneity and the change of many properties on mixing. The properties of a solution depend on the interactions between the particles of the solute, on the interaction between the particles of the solvent, and on the interaction between the particles of the solute and the solvent [47.5].

In the particular case of biological macromolecules, solubility is defined according to the solvent properties or solution–crystal equilibrium. In general the solvent is water or a buffer solution, so that the protein will have a proper chemical composition to bond to the solution at a specific pH value, or ionic strength (given by salts), and finally some additives (detergents, divalent cations, etc.). All these factors will affect the properties of the protein solubility in a different way. For instance, all soluble proteins in water or buffer solutions will keep hydrophobic amino acids inside the internal structure. On the other hand the hydrophilic amino acids will be distributed around the protein, exposed to the solvent. This process gives stability to the protein molecule and keeps the biological system in equilibrium with the solvent. As a consequence, the stability of any biomolecule in a solution will depend on the interaction between solvent and solute. The balance of these interactions could be modified by chemical and physical parameters such as temperature, pH, salts, additives, organic solvents, etc. The appropriate way to look at the physical or chemical behavior of macromolecular solutions must

Fig. 47.1 Solubility plot for thaumatin experimentally obtained at 18 °C

be by means of a solubility plot showing the variation of the solubility of the protein versus the variation of the crystallization factor (the concentration of a precipitating agent, pH or temperature). A typical solubility curve shows different areas of the phase diagram where different types of phase separation take place. Figure 47.1 shows an example solubility curve for thaumatin, obtained at 18 °C.

This plot is divided into different zones where the crystal growth process takes place. In the area located under the equilibrium curve, the molecules of the protein are freely distributed throughout the solvent. This means that many biomolecules are needed to saturate the system. In the upper part of this equilibrium curve, there is a parallel line where a quasisteady state is obtained. This area is called the metastable zone, where nuclei are forming and dissolving at the same time and two types of forces are participating in the process: surface and volume forces. In the nucleation zone, the crystal growth process takes place, and larger crystals will grow at lower supersaturation values. However, at very high supersaturation, the system is highly supersaturated and protein–protein interactions will occur at high velocity, yielding amorphous precipitation. It is worth mentioning that everything is controlled by the driving force known as supersaturation. This is related to the differences in the chemical potential of the sample and connected to the Gibbs free energy. There is another way of investigating the solubility behavior of biomacromolecular solutions: by evaluating the solubility of protein molecules as a function of temperature. This physicochemical parameter will give us additional

Fig. 47.2 Solubility plot as a function of temperature, the pathway from A to B is called isothermal growth and from A to C is called isotonic growth

information related to the stability of the protein molecule at a specific pH value. For instance, Fig. 47.2 shows a theoretical plot of solubility behavior versus temperature. This plot contains the same areas as those shown in Fig. 47.1.

From this curve it is possible to see two pathways which permit the solubility to be reduced: (1) traveling from the undersaturated region A to region B at constant temperature, (2) traveling from region A to region C while reducing the temperature. Both sides of this plot will permit the reduction of the solubility to obtain phase separation, and depending on the velocity, this solid phase could be a crystalline phase. We must take into account that there are several parameters that participate simultaneously in the crystallization process of a biological sample, and we must also take into account that understanding the nucleation step based on a solubility plot will give us the possibility of growing high-quality single crystals.

Nucleation is a major step in the crystallization process. It is primarily defined in terms of nuclei formation and size distribution. As soon as crystallites are detectable, the phenomenon is called crystal growth. During nucleation several events occur simultaneously on various time scales, namely: molecular conformation changes that take place in ≈ 0.01 ns, surface structure and defect displacements occurring within 1 ns, surface step displacement in 1 μ s, growth of one atomic layer in 1 ms, hydrodynamic transport in about 1 s, and finally homogenous nucleation, which needs no more than a few minutes [47.6]. Chemical and physical interactions between different molecules can be monitored,

but only some methods provide sufficient resolution in terms of particle size and time scale. Static and dynamic light-scattering methods have been employed to verify protein homogeneity and measure protein-protein interactions under precrystallization conditions. They have also been applied without a sophisticated data reduction scheme to predict protein solubility and crystallizability [47.7, 8]. As a consequence, the combination of spectroscopic and crystallographic data may provide an insight into the energetics of nucleation. The free-energy barrier of this process is controlled by the supersaturation value, which is normally the driving force and is related to the spontaneity of the system by (47.1).

$$\Delta G = - \left[\frac{\left(\frac{4}{3} \pi r^3 \right)}{\Omega} \right] k_B T \ln \beta + 4 \pi r^2 \gamma, \quad (47.1)$$

where Ω is the molar volume occupied by a unit in the crystal, r is the hydrodynamic radius of the macromolecule or the cluster, k_B and T are the Boltzmann constant and absolute temperature, respectively, and γ is the surface energy (expressed in units of J/cm²).

Supersaturation can be defined by its absolute value $\beta = C/C_e$, or its relative value, $\alpha = (C - C_e)/C_e$, where

Fig. 47.3 Theoretical plot for the nucleation phenomena

C_e represents the actual value of solubility at certain concentrations of precipitant and protein, i.e., one of the (x, y) values of the plot shown in Fig. 47.1. Nucleation behavior can be easily computed if we have the values of Ω at which the molar volume is occupied by a unit in the crystal from x-ray diffraction, and the hydrodynamic radius (r) from the hydrodynamic properties of the solu-

tion as well as the surface energy (γ), both of which are usually obtained by dynamic light-scattering methods. Figure 47.3 shows the theoretical behavior of the nucleation process, where surface and volume forces are competing. The result of the summation of both plots will give us the variation of the Gibbs free energy versus the size in units of the monomer radius [47.9].

47.2 Transport Phenomena and Crystallization

Transport processes, and in particular mass transport, are very important for crystal growth from aqueous solutions [47.10–12]. Mass and heat transport processes are critical to the final quality and characteristics of the crystals [47.13]. Many crystallogensis techniques have been explicitly developed for controlling the relative contributions of convective and diffusive transport in crystal growth [47.14]. During the active incorporation of ions or molecules into the three-dimensional lattice, density differences are generated in the proximal area of the developing faces, leading to convective flux in the surroundings of the crystal [47.15–17]. Convective transport of molecules competes with pure diffusive transport, and the in-

teraction between them will determine the way and the kinetics of nutrient presentation of the growing crystal.

Transport phenomena not only affect the nutrients of the crystals but also the rate of adsorption and incorporation of impurities, which affects the size, morphology development, and perfection of the crystal [47.18]. On the other hand, convective transport only occurs in the presence of gravity. Only then can heavier fluids fall and lighter fluids rise, letting convective currents emerge in the bulk of the solution. Other types of convection do exist, such as convection due to surface tension [47.19], but they are not significant in the crystallization process of solutions.

47.3 Classic Methods of Crystal Growth

Medium-sized single crystals with near-to-perfect habits made of molecular arrangements with no defects that produce well-resolved and intense diffraction patterns are the dream of every protein crystallographer. Four basic crystallization methods are presently at the disposal of crystal growers to grow such crystals. Like half a century ago in chemistry laboratories, crystallization assays can be set up either (1) in batch mode, (2) by vapor diffusion between hanging (or sitting) droplets and a reservoir of precipitant, (3) by dialysis across a semipermeable membrane or (4) based on free-interface diffusion at the interface of two liquids [47.20–23].

In batch crystallization, nuclei can form and grow immediately in a constant volume once all ingredients, i.e., protein, buffer, precipitant, and additives, have been mixed. An automated version successfully employs microliter droplets that are deposited under a layer of oil [47.24]. In the vapor diffusion method, a small volume of macromolecular solution

is equilibrated against a larger volume of precipitant. Equilibration occurs with the transfer (at constant temperature) of a volatile compound (usually water) until isopiestic pressure is reached [47.25]. Its rate is viscosity and vapor pressure dependent, and the volume of the initial protein solution decreases proportionally to the precipitant concentration difference. Most commercial crystallization robots employed for high-throughput applications dispense a great number of submicroliter volume droplets onto dedicated crystallization plates [47.26]. On the other hand, dialysis permits us to approach the equilibrium differently, and can reach the supersaturation zone more smoothly and in a better controlled manner [47.27, 28]. Also samples can be reused as long as they are not irreversibly denatured. This technique is not so popular, probably because samples smaller than a few microliters are difficult to handle and because it has not yet been automated. Finally, in Earth-based laboratories, convectional flow triggered by density differences restricts

the use of diffusion at the interface between macromolecular and precipitant solutions to small sample volumes contained in capillary tubes [47.29]. Free-

interface diffusion has been successfully applied in quasiweightlessness, where solutal convection is naturally weak [47.30].

47.4 Protein Crystallization by Diffusion-Controlled Methods

47.4.1 Crystallization in Microgravity Environments

Many years of experimentation with diverse crystals has confirmed the notion that, by minimizing convective mass transport, better quality crystals can be obtained, with improved mechanical and optical properties, reduced density of defects, and larger size.

How is it possible to suppress the natural convection in crystallogenesis? Nowadays, different approaches have arisen for removing or at least reducing it. One of them is crystallization of macromolecules in space, where in the absence of gravity, convection disappears. In the last decade, a new approach that involves the use of magnetic fields has appeared. Magnetic forces opposed to gravity can reduce natural convection inside solutions [47.31, 32]. Also, methods for crystallizing macromolecules in gels are good and well-accepted alternatives for eliminating natural convection [47.33].

It is natural to think that, at zero or reduced gravity, crystals with superior properties can be grown [47.18]. Is this possible? Observations and experimental data support the hypothesis that convective flows can be related to the introduction of statistical disorder, defects, and dislocations on growing crystal surfaces [47.34–36]. Convective transport tends to be variable and random, producing variations in the supersaturation levels in the environment of the developing faces, exposing them permanently to high levels of nutrients, similar to those of bulk crystallization. On the contrary, under microgravity, convection is suppressed and the concentration of nutrients at the interface of the crystal is reduced. Mass transport is purely diffusive, which for proteins is very slow, and a region of depletion of nutrients is established around the nucleus. Thanks to the absence of gravity, this zone is quastable. We can imagine one crystal in the center and the gradient of nutrients on the right-hand side and on the left-hand side aggregates and large impurities. In the right-hand part, nutrient molecules diffuse very slowly because of their size, lengthening the effect. On the left, impure molecules diffuse more slowly than monomers

do. As a consequence, the depletion zone acts as a *diffusive filter*, avoiding the incorporation of impurities into the growing crystal. Apparently, this is the principal mechanism for improvement in crystal quality under microgravity. This hypothesis is not only supported by the experimental data but also by mathematical models that explain the mass transport process involved. It has also been shown (in a particular case) that up to a 40% reduction of nutrient molecules near the nucleus can be achieved in the absence of gravity, relative to the bulk concentration [47.37].

In the past, the aim of convection suppression was the inspiration for many scientists who devoted their work to developing new techniques and devices. The first serious experiment for crystallizing macromolecules under microgravity was done by a German team under the direction of Prof. Littke in 1978. On that occasion, lysozyme and β -galactosidase were successfully crystallized by the liquid–liquid diffusion method in a series of reactors [47.38–41].

The progression made in this crystal growth area was hard and slow, owing to the sparse literature on experiments performed in microgravity during the 1970s and 1980s. Moreover, many results were unavailable to the research community because they belonged to private companies or because of the lack of communication between Oriental and Western scientists [47.18]. It was not until 1989 that the first formal scientific paper was published in *Science*, in which x-ray diffraction analysis of many crystals grown in microgravity was reported. They presented higher intensity/estimated error ($I/\sigma(I)$) rates through the whole range of resolution, and higher resolution values [47.42]. This article provided tangible proof that crystals formed in microgravity environments generate more data of higher quality, producing more precise structures.

How are experiments performed in microgravity? Nowadays many devices exist, based primarily on two techniques: vapor diffusion and liquid–liquid diffusion [47.43], and the thermal-induced batch technique has also been successful in growing some large crystals that gave very high resolution [47.44]. The experiments are performed by governmental space agencies

or private consortia, such as Payload Systems (USA), Intospace (a European consortium, recently dissolved), and Bioserved (a center for commercial development sponsored by NASA). Each consortium has developed its own devices for its experiments [47.43]. Among the vapor diffusion devices, the vapor diffusion apparatus (VDA), designed and built by Bugg and collaborators from Alabama University at Birmingham, USA [47.45,46], is the most commonly used device, with more than 25 missions. Although originally the device was very simple, it was possible to crystallize many diverse proteins, such as lysozyme, canavaline, bovine serum albumin, and others. Presently, newer and more complex versions of microgravity devices exist, offering major advantages and possibilities for controlled experimentation.

As mentioned above, experiments done in space do not evolve in the same manner as those performed on Earth. For example, for vapor diffusion experiments done in both environments, the equilibrium kinetics is different, and this difference is stronger in liquid-liquid diffusion experiments. In spite of this, the superiority of crystals grown in space compared with those grown under Earth's gravity has been established by comparison according to four well-chosen criteria. First, a *visual examination* is fulfilled (this is a subjective analysis based on observation of the crystal under the microscope). Then, the *sizes and the distribution* of those values in the experiment are analyzed. *Morphology* is another evaluation criterion, as many protein crystals grow with different crystalline habits depending on whether the process was done on Earth or in space [47.42]. Finally, the properties of the x-ray diffraction pattern generated by a crystal must be considered (as the internal order of a crystal relies on the growth kinetics).

Following these criteria, a number of advantages found in crystals grown in microgravity can be summarized [47.42,47,48]:

- Visual superiority.
- Larger crystals, many orders of magnitude larger than the biggest crystals grown on Earth [47.18].
- Higher resolutions achieved in x-ray diffraction patterns.
- Better $I/\sigma(I)$ signals (Wilson plot); in the entire range of the resolution, higher values of $I/\sigma(I)$ for microgravity crystals were found. However, the physical properties responsible for this observation are as yet unknown. Apparently, the reason is a lower defect density.
- Sharper x-ray diffraction intensity peaks, showing quantitatively the better internal order and perfection of protein crystals grown in space.
- Not only proteins can be crystallized in the absence of gravity, but also other macromolecules such as viruses (satellite tobacco mosaic virus), DNA, pharmaceutical targets (HIV reverse transcriptase) or membrane proteins (bacteriorhodopsin).
- Under microgravity, the sedimentation effect disappears. In space, crystals keep their defined and stable positions over long periods of time. It is therefore a favorable environment for multiple crystal growth, minimizing the superposition of diffusive fields and assuring more or less uniform access to nutrients by all faces [47.49]. Besides, the incorporation of microcrystals or three-dimensional nuclei by sedimentation into the growing faces is avoided.

On the other hand, among its main disadvantages are the cost and the waiting time. It is an expensive method and requires a lot of time since the missions are not daily and they last for many days, especially when consecutive experiments are desired. Therefore, the disadvantages of microgravity protein crystallization are: high cost, low reproducibility, low reliability, lack of correspondence between Earth- and space-based observations, and lack of understanding of microgravity observations. Finally, based on these disadvantages, we could say that nowadays most protein crystallization programs have been abandoned by the respective space agencies.

47.4.2 Crystallization in Gels

As early as the end of the 19th century, inorganic compounds were crystallized in gelatin or gels made of siloxane [47.50, 51]. Once the actual role of the gel was recognized, it was added to crystallization media to reduce convective flow [47.52, 53], favor mass transfer by diffusion [47.54, 55], and immobilize crystal nuclei in the network and suppress gravity-driven sedimentation [47.50, 51, 56]. After the first report by Low and Richards in 1954 of the use of gelatin in the crystallization of albumin [47.57], it took a while before inorganic and organic gels were reintroduced for protein crystallization [47.55]. This led the way to the production of crystals having many fewer defects. Indeed, protein and virus crystals grown in such gels have enhanced diffraction properties, including sharper Bragg reflections, higher

diffraction intensities compared with background noise, or a higher diffraction limit compared with crystals grown in solution [47.58, 59]. Despite the discovery of these benefits, gels are largely underexploited by protein crystal growers. The same holds for counterdiffusion [47.60, 61], a crystallization method in which capillary forces exerted in cylindrical tubes of small diameter strongly reduce convection and stabilize the concentration gradients that exist around growing crystals [47.62, 63].

47.4.3 Crystallization in Capillary Tubes

The aim of this section is to summarize technically simple and efficient crystallization methods for optimizing the quality of crystals of a variety of biological particles, including proteins, nucleic acids, multimolecular assemblies, and viruses. Crystallization assays in microporous, chemical or physical hydrogels (as mentioned above) or inside capillary tubes (as described here) only require inexpensive chemicals and simple laboratory equipment. Conditions identified by a preliminary sparse-matrix approach in solution can be readily transferred to gels or capillaries in an attempt to enhance the diffraction properties of crystals. Gels and capillaries are also convenient for crystal storage and transport. In the course of this study, novel gel-forming compounds have been tested and a novel crystallization method for reducing convective flow has been implemented. Furthermore, crystal content analyses by mass spectrometry have been performed in order to determine the limits of the impurity-sieving effect of agarose on the incorporation of isoforms in thaumatin crystals. Crystallization and crystallographic results obtained with small model proteins and large enzymes involved in gene expression are presented. The contributions of diffusive media and of counterdiffusion methods are discussed and practical recommendations given. Another way to reduce the natural convection under Earth's gravity is to incorporate gelled media into the solutions. In 1968, Zeppezauer and coworkers described the use of microdialysis cells, made of capillary tubes sealed with gel stoppers (polyacrylamide), to reduce convection in crystallization solutions to obtain better crystals [47.64]. Then, in 1972, Salemmé also succeeded in the crystallization of proteins inside a glass capillary tube [47.29]. He put a protein solution into contact with a precipitant agent and let the system reach equilibrium by counterdiffusion [47.38]. Some years later, ribosomal

subunits were crystallized successfully with the same setup [47.65].

After many years of investigation, Prof. García-Ruiz proposed the use of gelled media for crystallizing macromolecules by counterdiffusion. This technique combined the principle of reduced convection and the advantage of having a wide range of conditions in a single experiment [47.66]. All this progress allowed García-Ruiz and colleagues in 1993 to develop of a new technique called the gel acupuncture method (GAME) [47.67, 68]. This novel technique consists of the permeation of the precipitating agent solution through the gel and the penetration by capillary force into the capillary tube, filled with a protein solution, allowing for crystallization [47.68]. This technique is well known today, and various types of gels, capillary tubes, additives, and precipitating agents have been evaluated for its use [47.68, 69]. A difference from other methods is that inside a capillary tube there is not only one supersaturation level, thus precipitation zones will be found in regions of very high supersaturation, nucleation will happen at high supersaturation levels, and the growth of those nuclei will be found in regions of lower supersaturation levels. This increases the probability of finding the right conditions for crystallization [47.70]. Other advantages are the possibility of crystallizing proteins inside capillary tubes ready for direct x-ray diffraction data collection, avoiding the usual physical manipulation of the crystals and thus reducing the risk of breakage at the moment of mounting them or transporting them to the synchrotron [47.71], or the use of cryoprotectors and/or heavy metals inside the crystallization solutions by using a counterdiffusion method in capillary tubes [47.72].

Through the counterdiffusion methods in capillary tubes it was possible to crystallize diverse proteins of different molecular weight and a wide range of isoelectric point, viruses, and protein–DNA complexes [47.73]. In addition, thanks to the advances in structural genomics, a new device was developed for executing multiple and independent experiments, which is appropriate for effective screening of crystallization conditions of biological macromolecules [47.71]. It combines the benefits of multiple conditions in one capillary, thereby increasing the chances of finding the optimal ones, with the possibility of direct x-ray diffraction analysis in the device. All these advantages have converted this device into the first totally all-inclusive system since the initial steps toward data collection for structural analysis [47.71].

47.5 New Trends in Crystal Growth (Crystal Quality Enhancement)

At the beginning of the new millennium, several structural projects were devoted to finding a cure for diseases based on knowledge of the three-dimensional structure of specific biological targets; the problem has been to obtain high-quality single biocrystals to be investigated by x-ray diffraction. There are several novel approaches to overcoming the poor quality usually obtained in biological crystals for high-resolution x-ray crystallography. Some of these are the application of an in-situ internal electric field in the crystal growth process [47.74–77], the use of external electric fields in protein crystallization [47.78–81], the application of strong magnetic fields and high pressure [47.82–84], the combination of electric and magnetic fields [47.80], the use of ultrasonic fields [47.77], the use of femtosecond laser irradiation (FSLI), and the solution-stirring (SS) method [47.85], as well as addition of nucleants to crystallization droplets [47.86–91]. Basically, the idea behind all of these approaches is related to placing the system in the nucleation regime in the solubility plot and providing the system energy for spontaneous first nucleation. In order to separate the nucleation phenomena and the crystal growth process, it is necessary to look for a precise technique to investigate the limits of these two processes. In this regard, dynamic light-scattering methods usually help to define those areas where nucleation is happening [47.8, 92–94] while atomic force microscopy or video microscopy is appropriate to investigate mechanisms of crystal growth (reviewed later).

47.5.1 Crystallization Under Electric Fields

The study of the effect of electric fields on protein crystallization had not been explored until the pioneering work on estradiol 17 β -dehydrogenase electrocrystallization [47.95]. Recent studies performed by Aubry and coworkers, with electric fields external to the crystallization solution, showed that it is possible to reduce lysozyme nucleation and increase the crystal growth rate. Then, the same group evaluated the crystal growth kinetics and found an increase in the protein concentration near drops that were close to the cathode [47.75]. Nanev and Penkova [47.76] came up with similar results when crystallizing lysozyme by batch method in the presence of an external electric field. They reported that lysozyme crystals grew with a definite orientation towards the cathode. Recently a full review of the ef-

fect of electric fields on protein crystallization has been published [47.77].

Biological macromolecule crystallization, in the presence of an internal electric field, uses a similar setup to that used by the gel acupuncture method, except that an inert electrode (Pt) is introduced into the capillary tube and comes into contact with the protein solution, and another electrode is set collinear to it, in the gel [47.74]. Protein molecules are charged since the pH solution is far from the protein's isoelectric point. When a small direct constant current is imposed on the system, a potential difference is established between the electrodes, provoking an orientation effect over the macroions (protein molecules). Lysozyme and thaumatin crystals were found to be firmly attached to the anode during the crystallization process.

To understand what is going on when the potential difference is established, it is important to comprehend how the solution is structured and the effects the electric field has on it. The proposed hypothesis for nucleation inside the capillary tube, in contact with an anode, considers the presence of an electric double layer in the surroundings of the electrode. When an electrode comes into contact with an electrolyte solution, the ions feel asymmetric forces and order themselves, forming an electric double layer. The first layer is composed of water molecules with their dipoles oriented, whereas the second layer is composed of counterions. Positively charged protein molecules need a negative ion for favorable protein–protein interactions, for example, CL^- for lysozyme [47.96] or potassium sodium tartrate for thaumatin [47.97]. The potential difference established in the cell allows the migration of anions of the precipitating agent into the capillary tube, encouraging interaction with the protein molecules in the solution, in the first instance. Then the counterions of the electric double layer will act as supports for positively charged protein molecules or nuclei, allowing the crystal grow over the anode. This behavior was not found when a cathode was placed inside the capillary tube [47.74].

This technique is very new and has only been evaluated with model proteins, such as lysozyme and thaumatin. However, it seems very promising as crystals with similar quality to those grown with the gel acupuncture method were obtained, but with shorter nucleation-induction times and without affecting three-dimensional growth rates [47.74]. This is

very interesting from a biotechnology point of view, since shortening the crystalline production time is desirable.

The reduction of the induction time in crystallization had also been observed by *Moreno* and *Sazaki* [47.79]. Lately, these scientists have studied the effect of an electric field with a different setup, using the batch method and with parallel electrodes. Despite these variations, they noticed an induction time three times shorter in the presence of an internal electric field, corroborating the results found with the gel acupuncture method plus an internal electric field [47.74]. Besides, for the same work, the benefit of nucleation control is remarkable, since they obtained fewer lysozyme crystals with homogeneous size distribution.

47.5.2 Crystallization Under Magnetic Fields

It is possible to reduce natural convection on the Earth with the help of magnetic fields. Depending on whether they are homogenous or inhomogeneous, the fields act upon a sample in different ways. Inhomogeneous magnetic fields are responsible for reducing the effective gravity that a solution feels through the action of a magnetization force [47.32]. If a magnetic field gradient is applied vertically, a magnetization force will be generated. When this force opposes gravitational force, a reduction of vertical acceleration (effective gravity) is obtained. Hence, a decrease in natural convection is accomplished.

With a mathematical model of a crystallization system under a magnetic field, the concentrations of macromolecules in the surroundings of a growing crystal were estimated [47.98, Fig. 2], verifying that a magnetic gradient of $-685 \text{ T}^2/\text{m}$ reduces convection by 50%, while a magnetic gradient of $-1370 \text{ T}^2/\text{m}$ practically eliminates convection, producing similar conditions to that of microgravity [47.98]. Experimentally, high-quality high-resolution crystals were obtained, in agreement with the mathematical model [47.99]. Moreover, *Wakayama* and colleagues found that, in the presence of a magnetizing force opposite to g , fewer lysozyme crystals were obtained than in the absence of the magnetic force [47.32].

When a homogeneous magnetic field is applied, high-quality crystals are also observed [47.100], even though the mechanism involved is different. An increase in viscosity near the growing crystal was observed when a magnetic field of 10 T was applied [47.101, 102]. This increase in viscosity means that there is a reduction of natural convection inside the solution. Furthermore,

an orientation effect was observed upon the crystals formed under high magnetic fields [47.31, 32].

More recently, in another study, the decrease of the diffusion coefficient of lysozyme inside a crystallization solution under a homogeneous magnetic field of 6 and 10 T was evaluated [47.103]. All these observations are interrelated and are the consequence of the orientation effect by the magnetic field at a microscopic level. In a supersaturated solution, proteinaceous nuclei are suspended in the solution bulk, and sediment upon reaching an adequate size, which depends on the magnitude of the magnetic field applied. These nuclei act as blocks, avoiding the free diffusion of monomers, turning the solution more viscous and as a result reducing convection [47.103].

The research field of crystal growth under magnetic fields is relatively new and needs more study. A lot of things still remain to be understood about the effects of magnetic fields (both homogeneous and inhomogeneous) on macromolecular solutions. Evidently, a strong external magnetic field induces a magnetizing force, increases the viscosity of the protein solution, orients the growing crystals, and affects the growth process in a complex manner. All these phenomena seem to favor the resulting crystal quality, although a more complete investigation is needed to understand the mechanism better [47.102].

Finally, it is worth mentioning that the use of strong magnetic fields is still very expensive to be performed only in crystallization experiments. Maintenance of the superconductive magnets and the magnet itself are limiting factors for economic reasons. However, there are recent publications that have demonstrated that applying only a strong magnetic field, coupled with growth in a gel, improves the resolution limit as well as the crystal quality [47.104]. The combined effects of a magnetic field and magnetic field gradients on convection in crystal growth were published by *Wakayama* and colleagues [47.103, 104].

More recently a novel experiment using a popular magnet usually used for nuclear magnetic resonance (NMR) commonly used in chemistry laboratories was published [47.105]. This combined the batch method in gels under the presence of strong magnetic fields of 7 and 10 T in capillary tubes inserted in silicon hydrogels. A significant effect on the orientation of the crystals was noticed after 48 h in the presence of a 10 T magnetic field. The size of the crystals of lysozyme, thaumatin, and ferritin was improved while the number of crystals was decreased compared with the control. For instance, the crystal quality of thaumatin reached 1.15 \AA resolu-

tion, compared with the control which produced crystals of the same thaumatin at 1.7–1.8 Å resolution.

47.5.3 Combining Electric and Magnetic Fields

The simultaneous effect of magnetic and electric fields is a new field of research. Depending on the configuration of the system, great advantages can be acquired, such as homogeneity in crystal size, thanks to apparent suppression of secondary nucleation events, permitting the continuous growth of previously formed nuclei [47.103, 106]. Also, an orientation effect is noticed when the magnetic field is parallel to the electrodes, having the same effect as described in previous works [47.79, 80].

47.5.4 Robotics and High-Throughput Protein Crystallization

In the last few years, genomic advances have encouraged high-throughput structural biology studies. So much so that it has received the name of structural genomics and many huge public grants have been given to academic laboratories and private enterprises, such as pharmaceutical industries, around the world. The projects are diverse and extend from the study of the structure–function relation of proteins, through the mechanisms involved in protein folding [47.107], to the more pragmatic approach of rational drug design based on the structure of target molecules [47.108]. X-ray diffraction crystallography is critical in these studies, being the battle-horse in such initiatives. In this way, the crystallogenes of biological macromolecules arises as a vital step in the whole process, although it is the most complicated and last understood step in structural biology. In this section some aspects involved in high-throughput crystal growth of biological macromolecules will be reviewed.

The growing of crystals of biological macromolecules in large quantities takes place in several steps: protein production in large amounts (by heterologous expression or from its natural source), purification, crystallization trials, and their corresponding inspections. Since many proteins are evaluated at the same time it is mandatory to have automated systems that accelerate the work, while at the same time they should be trustworthy since the efficiency of each step affects the next one.

Heterologous protein production is almost completely automated for massive aims. This includes

cloning, transformation, and gene expression. These stages involved DNA molecules and, thanks to their high stability, they can be automated easily [47.109, 110]. Nevertheless, there is not yet a totally automated system for protein purification on a large scale with applications in structural biology. Proteins differ in their expression levels, solubility, and physicochemical properties, so that most scientists prefer to adopt a combination of manual techniques to obtain pure proteins. Despite this, many biotechnological companies have developed more integral solutions for large-scale purification. For example, Syrrx (San Diego, USA) uses a purification system developed at the Genomics Institute of Novartis Research Foundation, which combines centrifugation and robotized sonication with a system of column chromatography arranged in parallel, which is able to purify 96–162 proteins per day [47.110]. Affinium Pharmaceuticals (Toronto) has also developed an integral purification system. Proteomax covers all the steps, from the cellular extract processing to the pure concentrated sample, ready for analysis. This equipment can clarify the lysate, perform column chromatography, and desalt and concentrate samples, giving in the best cases a pure protein ready for structural studies. So many automated steps results in very useful purification equipment for large-scale studies [47.108].

Structural biology laboratories are capable of handling more than 1000 different proteins in a month. As a consequence they require the maximum possible automation of every stage, including crystallogenesis. This is not such a big problem, particularly considering that the vapor diffusion and microbatch crystallization techniques are the most frequently used. Therefore, diverse robots that can perform these functions exist on the market. Decode Biostructures produces ROBO-HTC, composed of a robot that prepares all different conditions (Matrix Maker) and another robot that dispenses the drops. Douglas Instruments is responsible for ORIX 6, which performs vapor diffusion with sitting drops or microbatch assays. This robot can process about 240 cells per hour. Another commonly used robot is Mosquito, from Molecular Dimensions. Mosquito is built by TTP LabTech, of TTP Group plc, one of the most successful technology companies in the world. This robot contains a set of precision micropipettes mounted on a continuous band, which deposit small volumes from 50 nl to 1.2 µl. Moreover, the micropipettes are disposable, avoiding cross-contamination problems and exhaustive washing. The robot dispenses drops for microbatch or vapor diffusion, and hanging- or sitting-drop crystallization experiments. Also, it can

be used with 96-, 384-, and 1,536-well plates, and comes with an easy-to-use software system that can be programmed.

Once the assays are set for incubation, regular inspection is required in order to find the adequate conditions for obtaining high-quality crystals. This is the most arduous part of high-throughput crystallization. For any one protein 1000 experiments are needed, on average, to obtain an appropriate crystal for x-ray diffraction analysis [47.108]. Many companies use human inspection, a very tedious and laborious step, so the idea of designing an automated inspection system is very tempting. An ideal inspection system should have the following characteristics:

1. The identification and elimination of clear drops, with 0% error (without risk of losing any crystals)
2. The capture of kinetic data (of the growing process or precipitation versus time)
3. The ability to distinguish crystals from precipitates and to find crystals inside precipitates in most cases
4. The determination of size and form of the crystal
5. The ability to improve points 3 and 4 based on *internal learning* (databases)

Some promising advances in image technology have been made by Decode BioStructures, which offers the *Crystal Monitor Workstation*. This equipment has a stereoscopic microscope, digital camera, voice control, and a database interface and can be coupled with ROBOHTC (from the same company). There also exists *Crystal Score* by Diversified Scientific, which provides a microscope over a motorized plate. It comes with a device that counts and sizes the crystals. RoboDesign has two options on the market: RoboMicroscope II, which can localize the drops, focus them, capture a color image, and store them automatically, while CPXO can classify drops into clear, precipitated, with crystals, and other categories.

Some of the advantages of automated image capturing are the high frequency with which images are registered, at precise times, and the possibility of evaluating them with diverse computer software, and applying artificial intelligence. Although the equipment does not have human experience it can be trained to develop its own database. However, in the end, there is no system that can totally ignore human inspection. Crystals are very difficult to obtain and, as long as an automated system with 0% false negatives does not exist, the human eye will be indispensable [47.108].

So far the advances and problems of high-throughput structural biology have been mentioned in

a general way. However, most of those studies are on soluble proteins. Membrane proteins entail other kinds of problems, as previously mentioned (in the membrane crystallization section).

What are the specific challenges of membrane protein structural biology? Diverse stages can be mentioned, such as protein production, purification, and crystallogenesis. Unlike soluble proteins, where more than 90% of the new protein structures come from recombinant samples, membrane proteins obtained from molecular biology techniques make up less amount than 50% [47.111]. This is in part because the strategies developed for overexpressing proteins are designed for soluble ones and do not favor integral membrane proteins [47.109]. The synthesis of membrane proteins makes use of the cell's secretory system, certain directionality, and their insertion inside membranes [47.110, 112]. Besides, many cells are not equipped to withstand such a flux in new membrane proteins, which saturate their secretory pathways and generate inclusion bodies in the cytosol or toxic intermediates for those cells. So, the choice of the expression system is an important issue in the production of membrane proteins.

Prokaryotic integral proteins can be expressed in prokaryotic systems with promising results. Some examples are structures of ionic channels [47.113] and certain proteins from the outer membrane [47.114], among others. On the contrary, eukaryotic membrane proteins overexpressed in prokaryotic organisms have been harder to achieve [47.115], since prokaryotic membranes have a different lipidic composition and can have a hostile environment for heterologous proteins. Besides, posttranslational modifications are necessary for correct folding of eukaryotic proteins or their insertion into membranes, but these are absent in prokaryotic cells [47.116]. Despite this, some successful isolated examples do exist, such as the in case of an enzyme bound to mammal membranes overexpressed in *E. coli*, when it was crystallized [47.117] and its structure solved [47.118], or the overexpression of a eukaryotic receptor coupled to G-protein in *Halobacterium salinarum* [47.119]. On the other hand, yeasts are good overexpression systems for eukaryotic proteins since they are easy to handle and powerful genetics tools [47.120, 121]. Mammal cells are the best choice for preserving the structural and functional integrity of mammal membrane proteins. However they are expensive and very complex to use, and as a result they are the last choice.

With regard to purification, detergents are usually used to dissolve membrane proteins. The choice

of detergent is essential, especially when designing studies on a large scale. Ideally a detergent should solubilize the membrane protein without forming aggregates [47.122]. An appropriate detergent is one that can selectively stabilize the native structure of proteins [47.123]. Every protein behaves in a particular way, which means that a specific purification protocol is needed for each one. This concept is in opposition to a *unique measure for all*, the motto of *en masse* experiments. Diverse strategies have been thought up to resolve this, like fusing a protein which has a certain affinity for a ligand to the end of a membrane protein that one wants to overexpress in order to facilitate its purification [47.124, 125].

Once pure, integral proteins are ready for crystallizing. Two alternative paths can be applied:

- 1) Crystallize the protein–detergent complex directly
- 2) Incorporate the protein once again into a lipidic bilayer environment, previous to its crystallization

Most of the structures solved by x-ray diffraction analysis come from crystals formed by the first path, by vapor diffusion or microbatch techniques. The method is similar to that used on soluble proteins but in this case the solute is the detergent–protein complex [47.122]. The use of robots simplifies the handling of these mixtures. The other path consists of restoring the membrane

proteins to a lipidic bilayer environment, before setting the crystallization experiments. This approach has its major model in the lipidic cubic phases method, as explained previously [47.126]. Automated equipment that can use this criterion for high-throughput membrane protein crystallization is under construction [47.127].

Finally, we can understand how the advances in the processes involved and the automation achieved in recent years have influenced the development of structural biology throughout the world. Many laboratories can successfully clone, express, purify, and crystallize soluble proteins on a scale that was unthinkable years ago. Nevertheless, there is still much to control and predict in many different stages of the general process. In relation to soluble proteins, the process for integral membrane proteins has not been achieved. In the near future, the problem of the amount of protein available for crystallization must be overcome by increasing protein production levels and improving the system of purification, especially the detergent choice. All this will help to obtain more successful crystallization trials. Besides, studies of the mechanisms that rule the process will aid in its scaling up and automation. Moreover, so many crystallization experiments will enrich databases and in consequence it will be possible to extract the tendencies and crystallization patterns. This will be a valuable ability for structural genomics, particularly for the aim of crystallizing new proteins.

47.6 2-D Characterization via Atomic Force Microscopy (Case Study)

47.6.1 General Overview

Understanding the nucleation and crystallization processes and the control of size and quality of macromolecular crystals of different proteins for structural investigations in biology and biomedical sciences is still a challenge in many laboratories worldwide. Particularly, the mechanisms of crystal growth are important in order to understand the history of the crystallization process. The pioneering efforts devoted to this investigation of those mechanisms of crystal growth were done by using scanning electron microscopy methods, examining the surfaces of lysozyme crystals as well as model proteins and virus particles, and deducing recent mechanisms of crystal growth [47.128–141], as reviewed by McPherson et al. in 2000 [47.142]. These results showed that crystal growth occurred by a lattice defect mechanism at low supersaturation and by two-

dimensional nucleation at high supersaturation. Step velocities and two-dimensional nucleation rates were obtained, and their dependence on supersaturation was compared with theory. Preliminary results on the early stages of nucleation and the phenomenon of cessation of growth have been presented. More recently, atomic force microscopy (AFM) has become a common tool in biophysical studies of proteins (mainly due to its ability to perform characterizations near to physiological conditions) [47.143–151]. Tertiary and quaternary structures, forces driving folding–unfolding processes, and secondary structure elements can be studied in their native environments, allowing a high resolution level associated with small distortions. It is important to remark that surface characterization techniques are not limited to AFM. Several groups have carried out insightful electron microscopy characterizations. Another prolific method has been interferometry, in particular two-beam

Fig. 47.4 Conceptual plot for protein crystal growth mechanisms observed by atomic force microscopy (designed by Dr. Gen Sasaki, Tohoku University Japan)

and phase-shifting methods, with several recent improvements. However, as a case study and reflecting the expertise of one of the authors, AFM methods coupled to electrochemical techniques will be revised in this chapter.

From the crystal growth viewpoint, we can use atomic force microscopy to show different areas where these crystal growth mechanisms are obtained on the solubility plot. Figure 47.4 shows those areas where high-quality single crystals can be obtained and their mechanisms of crystal growth can be studied by these atomic force microscopy methods. Knowledge of the limiting areas A, B, C, and D permits us to explain why a crystal that grows at high supersaturation will diffract the x-ray radiation poorly (due to adhesive crystal growth mechanism). On the contrary, crystals that grow at intermediate and low supersaturation values will diffract the x-ray radiation properly. The reason for this enhancement of crystal quality is that these crystals will grow by the following mechanisms of crystal growth: island growth or spiral growth. This plot also shows the best way to produce crystals of high quality by varying the temperature as a crystallizing parameter (as shown in Fig. 47.2). This overview image of the crystal growth mechanisms shown in Fig. 47.4 also explains why we can produce high-quality single crystals by microseeding methods. For instance, if one crystal nucleates at high supersaturation, the crystal growth cell will be filled with tiny, poorly shaped crystals. Most of the time these crystals will be poor scatterers of the x-ray diffraction due to the adhesive crystal growth

mechanism, which controls the crystal growth process at the beginning of the nucleation phenomena.

We can infer from Fig. 47.4 that the crystal will grow at the beginning by adhesive crystal growth at high supersaturation, and then the supersaturation will be reduced by the system itself (due to mass consumption). Then the crystal will continue to grow by island growth, finishing up with spiral growth at the end. This type of crystal is not available to diffract x-ray radiation (due to its poor internal crystalline order). However, since they finish growing by island or spiral growth mechanism, these crystalline species can be used as a source of microcrystals to be added to preequilibrated droplets by using the microseeding method, as pointed out by *Stura and Wilson* in 1991 [47.152].

47.6.2 Coupling AFM and Electrochemistry for Protein Crystal Growth

Nowadays, most atomic force microscopes are coupled to electrochemical devices (potentiostats and galvanostats). So, we can use these techniques from electrochemistry to produce electrocrystallization in different ways. The first is to produce compatible nuclei on the surface of various electrodes (mostly graphite). Then a potential difference can be applied to reduce the solubility of the solution of the biomolecule. Unfortunately, not all proteins are suitable for electrocrystallization. The most promising biological macromolecules are those which contain some metals as cofactors or that are covalently bonded to porphyrin groups, some amino

acids or certain disulfide bridges. There are only a few cases where the idea of electrocrystallization has been applied to some biological macromolecules. The pioneering work was performed on the crystallization of human placental estradiol 17 β -dehydrogenase, published by *Chin et al.* in 1976 [47.95]. There was another group who investigated the codeposition of electrocrystallized calcium phosphate and bovine serum albumin on the surfaces of titanium alloy (Ti-6Al-4V) under different conditions. Infrared (IR) and ultraviolet (UV) spectra showed that: (1) the content of the protein formed by electrochemical coprecipitation in the solution of calcium phosphate was higher than that formed by simple absorption; and (2) the protein formed at high direct current was more than that at low direct current. These results provided useful information about biocoating techniques of prosthetic implant materials [47.153]. The second approach focused on real electrocrystallization and was done by *Moreno and Rivera* [47.154]. They investigated the role of electrochemical processes on iron and CdSO₄ in the crystallization of horse spleen ferritin by using the cyclic voltammetry technique. It was found that, although both species exhibited important redox properties in the presence of an external applied potential, CdSO₄ played a leading role not only in the nucleation process but also in the growth behavior and morphology control of ferritin crystals.

47.6.3 AFM Characterization by Protein Immobilization by Means of Polypyrrole Films Deposited on Different Electrodes (HOPG and ITO)

Enzyme immobilization on electrode surfaces has been limited to soluble enzymes [47.155, 156]. However, recent developments in protein crystallization have created an important interest in the study of solid-state electrochemistry of protein single crystals in order to understand the mechanisms of crystal growth. Unfortunately, the fixation of these monocrystals to an electrode surface is difficult since the monocrystals break easily under mechanical pressure, and therefore they cannot be immobilized as other inorganic crystals [47.157, 158]. From this point of view, it is feasible to grow *ex situ* redox metalloprotein single crystals (such as catalases, ferritins, cytochromes, etc.) so that they can be introduced into the fluid cell of the atomic force microscope (AFM). In order to immobilize these crystals we can use polypyrrole (ppy) films deposited on highly oriented py-

rolytic graphite electrodes (HOPG) or indium-tin oxide electrodes (ITO) for structural investigations by AFM techniques. It is worth mentioning that ppy films are conductive and therefore their application as chemical cements will expand the number of future structural investigations into soft biological single crystals.

In general, we can fix any type of biocrystals by using the method of *Hernández-Pérez et al.* (2002) in which the polypyrrole film had been used as chemical glue for AFM investigations [47.159]. Figure 47.5 shows a case study in which we can see a ferritin monocrystal chemically fixed to a HOPG electrode by means of these ppy films. Recently, cytochrome c has been one of the most studied proteins in electrochemistry due to its electron-transfer properties and capability of being used as a solid-state electron-transfer device [47.160]. Even though only bovine cytochrome c is commercially available, its three-dimensional structure has recently been published at 1.5 Å resolution [47.161]. Therefore, in the near future this promising, natural electron-transfer protein can either be used for electrocrystallization investigations or as an electric biosensor component [47.160]. Pyrrole molecules can be polymerized in aqueous solutions by mixing 0.077 M pyrrole solution and 0.34 M LiClO₄ and applying a current of 50 mV/s in an electrochemistry AFM fluid cell (Veeco Co., Santa Barbara, USA). Figure 47.5a shows the surface of the HOPG electrode

Fig. 47.5 (a) 12×12 μm² scanning AFM image of the HOPG surface. (b) 12×12 μm² AFM image of the HOPG surface after polymerization of the pyrrole. (c) Full optical image of the ferritin crystal when scanning and after polymerization of pyrrole. (d) 12×12 μm² scanning AFM image of the ferritin crystal surface

without polypyrrole films. On applying a potential difference, the pyrrole polymerizes and the morphology of the HOPG surface is changed (Fig. 47.5b). Figure 47.5c shows an overall image of ferritin crystals obtained by batch mixing method with 1 : 1 : 1 ratio 0.1 M cadmium sulfate/0.5 M ammonium sulfate, ferritin solution of 20 mg/ml, and pyrrole/LiClO₄ mixture as mentioned above for polymerization. This polymerization of pyrrole was performed by means of a fluid cell in an EC-AFM Nanoscope IIIa. Finally, the AFM image of the surface of this ferritin crystal is shown in Fig. 47.5d. This image is different when compared with the one containing the polypyrrole. This experiment is particularly important because we can see from that image that polypyrrole film will surround the crystal so as to fix it

properly onto the surface of the electrode. Later, after scanning the surface by AFM (Fig. 47.5d), we can see that there is no pyrrole on the surface of the biocrystal (ferritin), which means that the protein crystal has been fixed to the electrode by a chemical reaction with polypyrrole films (chemical glue) around it.

A novel idea is to grow large crystals on transparent electrodes (ITO for instance) by following the strategy previously described. Then a new solution of protein, precipitant, and additives can be added to the crystal fixed on the electrode. This tiny crystal can reach good sizes for structural research by neutron diffraction techniques. At the same time, having this type of fixed crystals on ITO or HOPG, we can say that an electron-transfer biosensor has been obtained.

47.7 3-D Characterization via X-Ray Diffraction and Related Methods

Protein crystallography is a part of the solid-state sciences which aims to solve the three-dimensional structure of biological macromolecules by means of the x-ray diffraction of single crystals [47.162–166]. The state of the art in the three-dimensional (3-D) structure of several proteins, nucleic acids, and polysaccharides is collected in the protein databank (PDB, initially administrated in Brookhaven National Laboratory, whose updated website is <http://www.rcsb.org>). This database is collecting all x-ray diffraction information for most of the biological macromolecules. A review of a variety and use of several databases has recently been presented by Einspahr [47.167].

The appropriate way to solve the 3-D structure begins by performing precise x-ray data collection. In order to perform this we must work with high-quality single crystals. As pointed out in Sect. 47.6, the better the crystal, the higher the resolution limit. The vast majority of proteins need to have a certain degree of purity to be crystallized. However, crystallization also depends on the molecular weight of the protein, the type of the protein, and even the method of crystal growth used to obtain the crystals. The first well-known case is the protein horse spleen ferritin. In order to produce wonderful cubic-octahedral single crystals, horse spleen ferritin must be purified to the extent of having just monomers in the solution (Fig. 47.6a,b). Otherwise the presence of a small amount of impurities will poison some crystal growth sectors, producing dendritic growth such as that shown in Fig. 47.6c. It is important to emphasize that nowadays we can also use twin

crystals in order to obtain the 3-D structure of almost any protein. It is clear that, using higher-quality single crystals, we can produce marvelous electron density maps or a wonderful structure (Fig. 47.7) of almost any protein. This figure shows the 3-D structure of cytochrome c from bovine heart obtained at 1.5 Å resolution [47.161]. It took that group nearly 2 years to crystallize this protein due to the existence of isoforms (which made the crystallization process difficult), only one of which was crystallized (native cytochrome). The only way in which we could produce suitable crystals of cytochrome c for x-ray diffraction was by means of the microseeding technique. The crystallization of membrane proteins, macromolecular complexes, and large assemblies is still a challenge.

Behind these beautiful structures is still a challenge: crystallization of membrane proteins and macromolecular complexes and assemblies. In this regard, in the near future, as mentioned in Sect. 47.5, the existence of robots and high-throughput techniques will help greatly. The real challenge will be how to predict accurate 3-D structure from de novo proteins, based on powerful databases of the three-dimensional structures of many biological macromolecules.

Finally, neutron-diffraction protein crystallography methods are also becoming promising powerful tools for 3-D structural characterization. Neutron diffraction provides an experimental approach for directly locating H atoms and hydration in proteins, a technique complementary to ultrahigh-resolution x-ray diffraction [47.168]. Recently, technical aspects as well as

Fig. 47.6 (a) Crystal of ferritin grown by the batch method using only a purified fraction of monomers. (b) Three-dimensional structure of horse spleen ferritin showing the variety of cubic elements of the symmetry. (c) Dendrite of ferritin containing a mixture of oligomers ◀ ▲

Fig. 47.7 (a) A perfect twin crystal of cytochrome c from bovine heart. (b) Image of the cytochrome structure obtained at high resolution (1.5 Å, PDB code: 2b4z) by Mirkin et al. 47.161

some potential applications and limitations of neutron protein crystallography have been reviewed [47.169].

New related methods coupling x-ray crystallography and scanning electron microscopy to obtain three-dimensional electron microscopy of macromolecular assemblies have also been published [47.170].

Among the various crystallization techniques, crystallization in gels has found wide applications in the fields of biomineralization and macro-molecular crystallization in addition to crystallizing materials having nonlinear optical, ferroelectric, ferromagnetic, and other properties. Furthermore, by using this method it is possible to grow single

crystals with very high perfection that are difficult to grow by other techniques. The gel method of crystallization provides an ideal technique to study crystal deposition diseases, which could lead to better understanding of their etiology. This chapter focuses on crystallization in gels of compounds that are responsible for crystal deposition diseases. The introduction is followed by a description of the various gels used, the mechanism of gelling, and the fascinating phenomenon of Liesegang ring formation, along with various gel growth techniques. The importance and scope of study on crystal deposition diseases and the need for crystal growth experiments using gel media are stressed. The various crystal deposition diseases, viz. (1) urolithiasis, (2) gout or arthritis, (3) cholelithiasis and atherosclerosis, and (4) pancreatitis and details regarding the

constituents of the crystal deposits responsible for the pathological mineralization are discussed. Brief accounts of the theories of the formation of urinary stones and gallstones and the role of trace elements in urinary stone formation are also given. The crystallization in gels of (1) the urinary stone constituents, viz. calcium oxalate, calcium phosphates, uric acid, cystine, etc., (2) the constituents of the gallstones, viz. cholesterol, calcium carbonate, etc., (3) the major constituent of the pancreatic calculi, viz., calcium carbonate, and (4) cholic acid, a steroidal hormone are presented. The effect of various organic and inorganic ions, trace elements, and extracts from cereals, herbs, and fruits on the crystallization of major urinary stone and gallstone constituents are described. In addition, tables of gel-grown organic and inorganic crystals are provided.

48.1 Gel Growth in Crystal Deposition Diseases

48.1.1 Gel Growth of Crystals

Recently, there has been increasing interest in crystal growth in gels on account of its suitability to grow crystals of biological macromolecules and in studies involving biomineralization. The gel method of crystal growth is probably the most simple and versatile technique, compared with other methods of crystal growth from solutions under ambient conditions [48.1]. In 1896, *Liesegang* first observed the periodic precipitation of slightly soluble salts in gelatin [48.2]. Later, this technique was used extensively to crystallize many organic, inorganic, and even biological macromolecules in various colloidal media. The gel method of crystallization is well described by *Henisch* [48.1,3], *Arora* [48.4], and *Patel and Venkateswara Rao* [48.5] as well as by *Lefauchaux and Robert* [48.6]. The present chapter aims to review crystallization in gels with a special focus on crystallization of compounds causing crystal deposition diseases.

48.1.2 Types of Gels

Gel growth is a particular case of solution growth where the solution is trapped in a polymeric structure. The gel is a loosely linked polymer of a two-component sys-

tem formed by the establishment of a three-dimensional system of cross-linkages between molecules of one of the components. The system as a whole is permeated by the other component as a continuous phase, giving a semisolid, generally rich in liquid. Gels can be prepared by a variety of techniques and materials. The most commonly used ones for crystallization are gels of silica, agar, gelatin, clay (bentonite), and polyacrylamide.

Silica gel is prepared [48.1] by mixing aqueous solution of sodium metasilicate and mineral or organic acid. Gelation takes place in times ranging from a few seconds to a few months, depending on the pH, temperature, and concentration of the gel solution. To form agar gel [48.7], agar-agar is dissolved in water (1–2% by weight) and boiled. When this solution cools down, gelation takes place. Gelatin gel is prepared [48.8] by dissolving gelatin in water, stirring at a constant temperature of 50 °C for 1 h and cooling to room temperature. A small quantity of formaldehyde is added to strengthen the gel. To prepare clay gel, powdered clay is slowly sifted on rapidly stirred water making a blend until about 9% clay has been added; the gel sets immediately. Polyacrylamide gel [48.9] is prepared by dissolving 3.99 wt % acrylamide and 0.02 wt % of a cross-linking agent in water. The solution is bubbled

with nitrogen and degassed by lowering the pressure. This results in a rigid transparent gel. Crystallization has also been attempted using other gels such as pectin, polyethylene oxide (PEO), polyvinyl alcohol (PVA), and tetramethoxysilane (TMOS) [48.1, 3–7].

48.1.3 Mechanism of Gelling

Gels can be formed by cooling of a sol, by chemical reaction or by addition of a precipitating agent or incompatible solvents. The time taken for the gelling process varies from minutes to days, depending on the nature of the reagents and its temperature, pH, and history. The mechanical properties of fully developed gels can vary, depending on the gel density.

In the case of silica gels, when sodium metasilicate (Na_2SiO_3) is dissolved in water, monosilicic acid and sodium hydroxide are produced initially as per the

following reaction

Later on, monosilicic acid polymerizes with the liberation of water. The process of polymerization continues, until a three-dimensional network of Si-O links is established. The hydrogen ion concentration (pH) plays a vital role in the gelling process. During polymerization, it is known that two types of ions, viz. H_3SiO_4^- and $\text{H}_2\text{SiO}_4^{2-}$, are produced, whose relative amounts depend on the pH. The formation of the more reactive $\text{H}_2\text{SiO}_4^{2-}$ is favored at high pH values. However, higher charge implies a greater degree of mutual repulsion. H_3SiO_4^- is favored at low pH values and is responsible for the sharp increase in viscosity. Very high or very low pH values inhibit gelation. Gelling mechanism regarding agar and TMOS gels are reviewed by Lefaucheur and Robert [48.6].

48.2 Experimental Methods

Crystal growth methods in gels fall into the following classes: chemical reaction, complex dilution, reduction of solubility, chemical reduction, and electrochemical techniques [48.5].

48.2.1 Chemical Reaction

This method is suitable for crystals which are mostly insoluble or sparingly soluble in water and which decompose before melting. Here, two soluble reactants are allowed to react inside the gel medium by incorporation of one of the reactants (I) in the gel, whereas the other reactant (II), which is used as the supernatant, diffuses into the gel medium (Fig. 48.1). The reaction inside the gel leads to the formation of an insoluble or sparingly soluble crystalline product. The basic requirements of this method are:

1. The gel must remain stable in the presence of reacting solutions
2. It must not react either with the solutions or with the product.

U-tubes are used, where the two reactants are allowed to react by diffusion into an inactive gel. This technique can also be adopted to crystallize compounds which have poor aqueous and organic solubility (uric acid and cystine) using the displacement reaction method [48.10, 11].

48.2.2 Complex Dilution

In this method, the material to be crystallized is first complexed in some reagents which enhance its solubility. It is then allowed to diffuse into a gel which is free from active reagents. As the complex solution diffuses through the gel it gets diluted. This results in a high supersaturation of the material to be crystallized and

Fig. 48.1 Reaction method (single diffusion)

hence nucleation and subsequent crystallization occurs. Crystals of mercuric sulfide, cuprous, and silver halides and selenium have been grown using this method [48.5].

48.2.3 Solubility Reduction

This method is generally used for crystallization of highly water-soluble substances. The substance to be grown is dissolved in water and incorporated in the gel before gelation. After the gel has been set, a solution that reduces the solubility of the substance (solute) is added as a supernatant solution to induce crystallization. Compounds which have low aqueous solubility can also be crystallized using this technique. Steroids which have low aqueous solubility have been crystallized using this technique by reducing the water content in the gel by incorporating an organic solvent [48.12]. During this process of crystallization, crystals can be observed in the supernatant solution above the gel due to the reverse diffusion of the precipitating solvent [48.13, 14].

48.2.4 Chemical Reduction

This method is particularly suitable for growing metallic crystals (Cu, Au, and Ni). The metallic salt is incorporated with the gel and an aqueous solution of a reducing agent is slowly allowed to diffuse through the gel, where chemical reduction takes place to form metallic crystals [48.5].

48.2.5 Electrochemical/Electrolysis

Gels can be used to crystallize metals by electrolysis. *George and Vaidyan* [48.15] reported growth of single crystals and dendrites of silver. Recently, *Muzikar et al.* [48.16] reported crystallization of microcrystals of gold. Here, a small current was passed between two gold electrodes through a silica gel doped with HAuCl_4 . Single crystals of gold of sizes ranging from hundreds of nanometer to hundreds of micrometer were grown by

this technique. *Muzikar et al.* [48.17] have also crystallized platinum particles and a platinum complex by an identical procedure.

48.2.6 Crystal Growth in the Presence of a Magnetic Field

The effect of a magnetic field (up to 3 T) on the crystallization of calcium tartrate [48.18] and strontium tartrate [48.19] has been reported. The magnetic field has the effect of reducing the number of crystals formed but helps in the growth of a few, larger crystals. Crystallization of cholesterol in gels in a magnetic field was studied by *Sundaram et al.* [48.20, 21]; it was found that the presence of the magnetic field reduced the nucleation time and number of crystals but that there was an increase in the size of the crystals grown.

48.2.7 Nucleation Control

During crystallization in gels, the growing crystals compete with one another for the solute atoms, leading to a reduction in crystal size and perfection. Hence, nucleation has to be suppressed until only a few crystals are formed. The use of a particular combination of reactants, to grow the required crystals, has been found to reduce the nucleation density [48.22]. Acid-set gels, choosing a particular acid (based on experiments with various acids), is known to yield larger crystals [48.22]. It has been reported that changing the gel structure by varying one or more of the parameters, viz. pH and density, and by gel aging, can decrease the number of nucleation centers [48.1, 3–7]. The use of an intermediate neutral gel is also found to slow down the reaction and thereby reduce the number of nucleated crystals [48.23]. In another method, the concentration of the diffusing reactant is initially kept below the level at which nucleation is known to occur and then increased gradually in a series of small steps. Crystals grown by this method are more perfect and larger than those grown otherwise.

48.3 Pattern Formation in Gel Systems

Pattern formation is widespread in nature and can be found in structures ranging from agate rocks and gold veins to the growth of bacterial rings in agar and gallstones [48.24–26]. A specific example discussed below is the Liesegang ring structure, discovered in 1896 [48.2]. When coprecipitated ions interdiffuse in

a gelatinous medium, the sparingly soluble salt may precipitate discontinuously in a spectacular pattern of parallel bands. The pleasing appearance of Liesegang bands, as well as their spatiotemporal distribution, has elicited a steady proliferation of publications on the subject [48.3, 27–29]. It is quite easy to produce the

Fig. 48.2 Disc and helical Liesegang rings of calcium phosphates in silica gel (after [48.32])

patterns in the laboratory. Liesegang rings can be produced in gels by diffusing one of the reactants into an inert gel medium containing another reactant. The simplest and usual way to perform a Liesegang ring experiment is to fill a tube with an inert semisolid medium which contains one of the reactants (B), called the inner electrolyte. The other reactant (A), referred to as the outer electrolyte, is poured over the gel column as the supernatant solution. Usually the concentration level of the outer electrolyte is maintained high to minimize the possible loss of ions due to evaporation and other such transport mechanisms during the experimental processes. It involves the formation of concentric laminated rings or bands clearly separated in the direction perpendicular to the motion of the front [48.27]. The structures, which are often rings in circular geometries and bands in linear geometries, are formed by the nonuniform spatial distribution of crystals in a precipitation reaction in a gel [48.28, 29]. Recently, *George* and *Varghese* reported the formation of triplet Liesegang ring patterns [48.30]. *Terada* et al. [48.31] described the formation of sheets and helices of stron-

tium carbonate in silica gel. Helical rings of calcium phosphates (Fig. 48.2) were formed in silica gels by the diffusion of calcium ions into a phosphate-containing gel [48.32].

Though *in vivo* occurrence is rare, chemical concentration, geometry of the reactant containers or vessels, temperature, pH, and the presence of impurities are the main factors that influence the formation of Liesegang rings [48.33]. The role of the gel during the formation of Liesegang rings is essentially passive, i.e., to prevent convection of solutions and sedimentation of the precipitate. The dynamics of the banding are very complex, involving the coupling of diffusion and precipitation processes in a nonequilibrium regime.

Theoretical models explaining Liesegang patterns fall into two broad categories. The first one, called the prenucleation model, is based on the classical feedback cycle of supersaturation, precipitation, and depletion as originally proposed by *Ostwald* [48.34]. In the second theory, the so-called postnucleation or competitive particle growth model, it is assumed that competition between growing particles can, by itself, produce periodic precipitation structures, even in the absence of strong external gradients. It is worth mentioning that all the theories share the assumption that the precipitate appears as the system passes through some nucleation or coagulation thresholds. However, the theories differ in their pre- or postnucleation assumptions. The main unresolved problem in all these theories is the understanding of the mechanism behind the transformation of the diffusive reagents A and B into an immobile coagulant. *George* and *Varghese* proposed a new model [48.30, 35–38] based on the prime assumption that the boundary that separates the outer ions and the inner electrolyte virtually migrates in the positive direction of the advancement of the type A ions. *Izsák* and *Lagzi* [48.39] proposed a universal law, which is also valid in the case of various transport dynamics (purely diffusive, purely advective, and diffusion–advection cases). The mechanism responsible for these structures is not yet fully understood. The interest in precipitate patterning phenomena is growing because of the suitability of their underlying dynamics for modeling many self-organization processes [48.40, 41].

48.4 Crystals Grown Using Gel Technique

Recently, there have been several reports on the crystallization of inorganic, organic, organometallic compounds, and metals apart from biological macro-

molecules using gels. Some of the compounds (except biological macromolecules) which have been crystallized using gels are listed in Table 48.1a,b.

Table 48.1 (a) Organic/organometallic crystals grown in gels

Crystals grown	Gel used	Method adopted	Studies carried out	Reference
2-Amino-5-nitropyridinium dihydrogen phosphate	Silica	Single diffusion	Crystal growth and growth rate studies by holographic interferometry	[48.42]
Ammonium hydrogen D-tartrate	Silica	Single diffusion	Bulk growth, habit	[48.43]
Antimony thiourea-bromide	Silica	Single diffusion	Dielectric constant, refractive indices	[48.44]
Asparagine monohydrate	Agarose, carrageenan, gelatin	Single diffusion	Crystallization and habit modification	[48.45]
Barium oxalate	Agar-agar	Double diffusion	Growth and characterization	[48.46]
Benzil, phenyl phenol	Sephadex	Single diffusion	Growth and characterization	[48.47]
Bis-(1,3,5-benzenetricarboxylato) dipyridine, Zinc(II) nitrate	PEO	Double diffusion	Crystal growth	[48.48]
Cadmium tartarate	Silica	Double diffusion	Optical absorption	[48.49]
Calcium malate-decahydrate	Silica	Single diffusion	Growth and characterization	[48.50]
Calcium L-tartrate-tetrahydrate (Mn ²⁺ doped)	Silica	Single diffusion	Doping and dielectric studies	[48.51]
(Sr ²⁺ doped)			Growth and characterization	[48.52]
Cerium lanthanum-oxalate	Silica	Single diffusion	Growth and characterization	[48.53]
Cholic acid	Silica, TMOS	Single diffusion	Growth and characterization	[48.54]
Dysprosium-gadolinium oxalate	Silica	Single diffusion	Optical absorption and fluorescence studies	[48.55]
γ -Glycine	Silica	Single diffusion	NLO studies, dielectric constant, photoconductivity	[48.56]
Iron-manganese levo-tartrate (pure and mixed)	Silica	Single diffusion	Growth and characterization	[48.57]
Lead (II) <i>n</i> -octa-, <i>n</i> -nona- and <i>n</i> -decanoate	Silica	Double diffusion	Morphology	[48.58]
β -DL-Methionine	Silica	Single diffusion	Growth and characterization	[48.59]
3-Methyl-4-nitropyridine-1-oxide	TMOS	Single diffusion	X-ray topography, NLO experiments	[48.60]
L-Phenylalanine	Silica	Single diffusion	Growth and characterization	[48.61]
Rubidium hydrogen-tartrate, strontium tartrate-trihydrate and tetrahydrate	Silica	Single diffusion	Growth and characterization, effect of magnetic field, (Pb) ²⁺ doping laser scattering tomography, magnetic susceptibility measurements	[48.62] [48.19] [48.63]
Strontium malate trihydrate	Silica	Single diffusion	Growth and characterization	[48.64]

Table 48.1 (b) Inorganic crystals grown in gels

Crystals grown	Gel used	Method adopted	Studies carried out	Reference
Ammonium chloride	Agarose,	Single diffusion	Periodic roughening transitions, AFM, interference contrast microscopy	[48.65] [48.66]
	Agar, gelatin, pectin, PVA	Reduction of solubility by reducing the temperature	Morphology	
Barium nitrate, boric acid, potassium dichromate	Agar, gelatin, pectin, PVA	Reduction of solubility by reducing the temperature	Morphology	[48.66]
Barium iodate-monohydrate, calcium iodate (mono- and hexahydrates)	Silica	Single diffusion Double diffusion	Growth and characterization Growth, doping microtopography	[48.67] [48.68]
Calcium tungstate	Silica	Double diffusion	Nucleation behavior, crystal morphology	[48.69]
Copper iodide	Silica	Single diffusion (decomplexation)	Growth and characterization Influence of CuI-HI complex	[48.70] [48.71]
Gold	Silica	Electrochemical growth	Backscatter electron diffraction	[48.16]
Lead bromide	Silica	Double diffusion	Growth	[48.72]
Lead carbonate	Silica	Double diffusion	Topotactic relationships	[48.73]
Lead hydrogen-phosphate	TMOS	Single diffusion	Influence of a polycrystalline precipitation zone	[48.74]
Lead iodide	Silica	Single diffusion	Morphology, microstructure	[48.75]
β -Lithium ammonium-sulfate,	TMOS	Single diffusion	Morphology, epitaxial phenomena	[48.76]
β -Lithium sodium-sulfate, lithium sulfate-monohydrate	TMOS	Single diffusion	Epitaxial, intergrowth phenomena	[48.77]
Platinum, ammonium-hexachloroplatinate(IV)	Silica	Electrochemical	Growth	[48.17]
Potassium ferrocyanide-trihydrate	Silica	Solubility reduction	Growth and characterization	[48.78]
Sodium bromate	Agarose, gelatin, silica	Single diffusion	Habit changes in various gels	[48.79]
Sodium chlorate	Agarose	Single diffusion	Selective growth and distribution of crystalline enantiomers	[48.80]

48.4.1 Advantages of Crystallization in Gels

The gel is an ideal medium for diffusion reaction and it acts as a three-dimensional crucible holding the crystals in fixed positions without overlapping. It

is a chemically inert, transparent system for growing good-quality crystals. It is possible to observe the entire growth process and the grown crystals can be harvested easily. Gel method allows effective control over factors such as density, concentration, and pH

of the medium. Since crystals grow in the absence of convection, gel growth provides a good simulation of space growth experiments, as in the case of growth of protein crystals. To get valuable clues towards understanding the biomineralization process, extensive studies have been carried out on carbonates of calcium, barium, and strontium in silica gel

medium [48.81–84]. Crystal growth in gels has been used to simulate the crystal growth process in sedimentary environments [48.85]. The simulation of pathological biomineralization in human organs using gel technique and the crystallization of biological macromolecules using gels are some of the recent advancements in this field.

48.5 Application in Crystal Deposition Diseases

Quite a variety of materials occur as crystals in living tissues and plants. Biomineralization is found extensively among living systems (eggs, mollusks, shells, pearls, corals, bone, and teeth). Biomineralization leads to crystals of uniform size and morphology with specific crystallographic orientation and properties [48.86]. The use of sophisticated methods of crystal identification including analytical electron microscopy has led to the discovery of crystals in the human body system. In organisms, some tissues calcify while others do not. The control over their nucleation and growth patterns and their location developed during evolution. Many of the mineral deposits assist in the regulation of the levels of free cations and anions in cellular systems. The presence of crystals in the human body produces both beneficial and harmful effects. Bone and teeth are composed of oriented nanocrystals of hydroxyapatite (HAP, $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$). Our sense of balance and acceleration is dependent upon the small calcite crystals present in the inner ear. Many crystal depositions in tissues are pathological, with unusual crystal forms and patterns of mineralization. The harmful effects of crystals result in the pathological deposition of crystals known as crystal deposition diseases.

48.5.1 Crystal Deposition Diseases

Crystal deposition diseases may be defined as pathological processes associated with the presence of microcrystals which contribute to tissue damage and cause pain and suffering [48.87]. The increasing incidence of crystal deposition diseases (Table 48.2) such as heart diseases, gout, gallstones, urinary stones, deposition in eyes, thyroid glands and bone marrow, etc., among our population has resulted in extensive research to understand their etiology and cure. Crystal nucleation frequently occurs in urinary tract, coronary artery tract, and gallbladder, resulting in formation of pathological urinary stones, atherosclerotic plaques, and gallstones, respectively. Although much technical advancements

have been made in the area of treatment of crystal deposition diseases, relatively little is known about the mechanisms involved in the process of pathological crystallization. Crystal deposition diseases are the result of a complex sequence of events that give rise to diseases through simple mechanical effects such as blocking ducts or hardening or weakening of flexible tissues. The formation of crystalline deposits in vivo is a multifactorial disorder, some of the significant factors being age, sex, occupation, diet, fluid intake, geographical location, and climate.

48.5.2 Significance of In Vitro Crystallization

Extensive research work is being carried out on the physicochemical aspects of compounds that are responsible for diseases such as atherosclerosis, gallstones, arthritis, urinary stones, etc., to study their growth mechanism and to find factors that can inhibit their growth in our body system [48.87–99]. One of the principal aims in this area is first to identify the mechanism of crystal growth conditions prevalent in biological systems and then to devise means of inhibiting the unwanted crystal growth. Despite the enormous research aimed at obtaining thorough knowledge of the genesis of pathological mineralization, the mechanism of crystal deposition remains largely unexplained. The main reason for this is the fact that mineralization in vivo cannot be observed directly. Also, in vivo experiments are possible only to a limited extent. Thus, the need to understand the situations that give rise to crystal deposition diseases has necessitated in vitro investigations of the crystalline components that lead to pathological deposits. The crystal growth process in gels is essentially like crystallization from solution and consists of the following three basic steps [48.81]:

1. Attainment of supersaturation of the salt to be deposited

Table 48.2 Location of stones/crystal deposits and the major crystals involved in crystal deposition diseases (*stones or crystal deposits are heterogeneous mixtures, some of them with more than one crystalline phase held together by a matrix)

Diseases	Location of the deposits	Major crystals involved*
Acute and chronic gouty arthritis	Joints of hands and feet	Monosodium urate monohydrate, uric acid
Acute pseudo gout	Knees, wrists, and pelvis	Calcium pyrophosphate dihydrate
Acute calcific periarthritis	Shoulders, hip, and spine	Hydroxyapatite (HAP)
Atherosclerotic arteries and veins	Arteries and veins	Cholesterol
Calcific pancreatitis	Pancreas	Calcium carbonate
Cholelithiasis	Gallbladder	Cholesterol
Urolithiasis	Stones in kidney, ureter, bladder, and urethra	Calcium oxalate-monohydrate (COM), calcium oxalate dihydrate (COD), dicalcium-phosphate dihydrate (DCPD), magnesium hydrogen phosphate-trihydrate (MHP), magnesium ammonium-phosphate hexahydrate (MAP), uric acid, urates, cystine, xanthine

Table 48.3 Constituents of crystal deposits grown in gel

Crystals grown	Gel used	Method adopted	References
Calcium carbonate	Silica, polyacrylamide	Double diffusion	[48.82, 90–94]
Calcium oxalate-monohydrate (COM) Calcium oxalate dihydrate (COD)	Agar-agar, agarose, gelatin, silica	Single, double diffusion	[48.89, 95–99]
Calcium sulfate dihydrate	Silica	Double diffusion	[48.100, 101]
Cholesterol	Silica	Single diffusion	[48.12, 102, 103]
Cholesteryl acetate	Silica	Solubility reduction	[48.12]
L-Cystine	Silica	Single, double diffusion	[48.11, 104]
Hippuric acid	Silica	Single, double diffusion	[48.98, 99, 105–110]
Hydroxyapatite (HAP)	Silica	Double diffusion	[48.111]
Magnesium hydrogen-phosphate trihydrate (MHP), magnesium ammonium-phosphate hexahydrate (MAP)	Silica	Single diffusion	[48.112, 113]
Monosodium urate-monohydrate (MSUM)	Silica, TMOS	Single diffusion	[48.114]
Octacalcium phosphate (OCP)	Polyacrylamide	Single diffusion	[48.115]
β -Sitosterol	Silica	Double diffusion	[48.116]
L-Tyrosine	Silica	Single diffusion	[48.12]
Uric acid	Silica, TMOS	Single diffusion	[48.117]
		Single diffusion	[48.10]

2. Nucleation
3. Subsequent crystal growth.

Investigations of either solution or solid-phase phenomenon will yield useful information regarding the etiology of calculi formation. The growth of crystals *in vivo* will be dependent on the same factors of solubility, nucleation, and growth rate as *in vitro*. It is also possible to study the effects of various inhibitors (covering a wide range of molecular weights) which are present in biological fluids, by knowing the growth and dissolution of the stones and stone mineral phases. The *in vitro* experiments simulate the conditions of stone formation artificially to infer the general principles of calculogenesis, which can shed some light on crystallogensis of pathological stones.

There is increasing interest in using gel as a crystallizing medium, as it acts as a medium for crystallization of biomolecules and to evaluate the processes of

biomineralization *in vitro* [48.6, 12, 32, 88, 89]. This is because of their viscous nature, providing simulation of synovial fluid, cartilage, and other biological fluids. This method also provides a convenient technique for assessing the effect of various compounds (present in the human body) in altering crystallization parameters such as aggregation of crystals and also the morphology of the insoluble particles. Hence, the gel method of crystal growth is considered ideal for studying crystal deposition diseases [48.88, 89].

48.5.3 Crystallization of the Constituents of Crystal Deposits

Table 48.3 lists references (1994–2006) related to the gel growth of materials that are constituents of calculi occurring in crystal deposition diseases. The references to earlier research contributions of this category are available in previous reviews [48.1, 3–6].

48.6 Crystal-Deposition-Related Diseases

48.6.1 Urinary Stone Disease

Generally, urinary stones are called renal stones, ureteral stones, bladder stones, or urethral stones, depending on their specific site of growth (Table 48.2). Variations in urine flow and tube blockage can cause local fluctuations in pH and concentration, leading to supersaturation of urine and subsequently crystal nucleation, growth, and aggregation resulting in the formation of calculi of different shapes and sizes (Fig. 48.3 [48.118, 119]).

The ultimate control of urolithiasis requires proper application of both approaches of stone removal and drug therapy. Drug therapy is mainly aimed at inhibi-

tion of growth and dissolution of the existing stone and prevention of stone recurrence. Hence, it is important to understand the mechanism of stone formation and identification of the inhibitors of different crystalline materials present in urinary calculi.

48.6.2 Theories of Urinary Stone Formation

There are various theories to explain the actual mechanism by which urinary calculi develop [48.89, 120–124]. *Randal*, in 1937 [48.125], reviewed all the existing theories and described that there must be some lesion in the renal pelvis to which a calculus could remain anchored during its period of growth. *Anderson and McDonald*, in 1946 [48.126], improved this theory by suggesting that the small crystalline deposits in the kidney reach renal papilla, come into contact with urine, and subsequently grow into stones by deposition of urinary salts. *Butt and Hauser*, in 1952 [48.127], concluded that crystalline constituents of the urine separate out of the urine because of the shortage of protective colloids. Crystalline deposits can also occur as a result of excessive excretion or abnormal pH of the urine. *Vermeulon and Lyon*, in 1968 [48.128], proposed an advanced theory by explaining the different stages such as supersaturation, nucleation, growth, aggregation, and retention involved in the formation of the

Fig. 48.3a,b COM urinary stones with (a) smooth surface (b) rough surface

stone. During the formation of urine, when it traverses the nephron, much of its water content is reabsorbed and urine gets supersaturated with respect to substances of limited solubility such as those found in stones. Molecular agglomerates of these substances having proper lattice orientation result in the formation of nuclei, or such nucleation can also be extraneous. When these nuclei attain critical size, they act as seeds and then grow into visible crystals. There are two different types of agglomeration, viz. primary and secondary agglomeration. Primary agglomeration is the growth of crystals on the surface or tips of crystals already formed. Secondary agglomeration is that which results from crystal-to-crystal collision. Primary agglomeration was recognized as a possible mechanism for the development of calculi [48.129, 130]. The conditions prevailing in the kidney are not conducive to the secondary agglomeration process, which is expected to play only a minor role in the formation of stones. The crystals, once formed, are retained inside the urinary tract and grow [48.89]. New small crystals originate upon the larger parent crystals and the matrix material binds crystalline material together, giving the stone its cohesive wholeness.

48.7 Calcium Oxalate

Calcium oxalate urolithiasis is the most common pathological condition associated with oxalate crystal deposition. Calcium oxalate crystalline deposits are also found in myocardium, bone marrow, and blood vessels. In urinary stones, calcium oxalate may exist as monohydrate (**COM**, $\text{Ca}(\text{COO})_2 \cdot \text{H}_2\text{O}$, 43%) or as dihydrate (**COD**, $\text{Ca}(\text{COO})_2 \cdot 2\text{H}_2\text{O}$, 20.5%). The formation of oxalate stone may be the result of supersaturation of the urine with its components, viz. calcium and oxalate, deficiency of inhibitors or the increase in concentration of promoters. Calcium oxalate forms mixed stones with calcium phosphates, uric acid, and magnesium ammonium phosphate hexahydrate (struvite, **MAP**, $\text{MgNH}_4\text{PO}_4 \cdot 6\text{H}_2\text{O}$).

48.7.1 Crystallization of Calcium Oxalate

COM was crystallized by *Girija et al.* [48.95] using calcium chloride and oxalic acid as the reactants in silica gel. Single-diffusion experiments yielded microcrystals of **COM** as seen in Fig. 48.4a. Crystallization using double diffusion yielded **COM** crystals of millimeter size. **COM** is a polymorphic crystal, and the crystals obtained

48.6.3 Role of Trace Elements in Urinary Stone Formation

The presence of certain trace elements may play a vital role in the formation of crystal deposition diseases. In recent years, the function of trace elements in the human body and the environment and their importance for medical practice have been increasingly recognized in the biomedical field. It has been suggested that some trace elements enhance the growth rate of deposits of crystalline compounds and that their high concentration in body fluids and tissues may be significant in this respect. One of the main problems is in determining whether nucleation is essentially homogeneous and takes place spontaneously from highly supersaturated fluids or whether it is heterogeneous and is initiated by some other agent such as trace elements (Mg, Pb, Ba, Fe, Sr, Zn, etc. [48.125, 127, 128, 131–133]). Impurities and diffusion limitations are suspected to play a major role in agglomeration. The process of aggregation through electrostatic forces would be expected to be controlled by the zeta potential of the particles, which is readily modified if any ion gets absorbed on the particles.

in this experiment were of prismatic (single, twinned, and bunched) morphology. These crystals enabled the measurement of Vicker's and Knoop microhardness and the values were found to be 192 and 73 kg/mm², re-

Fig. 48.4a–c **COM** single crystal in silica gel: (a) without any additives (b) in presence of cadmium, (c) in presence of zinc

spectively. *Achilles* et al. [48.89] designed a flow model of crystallization in gels, where crystal growth is performed from a flow of supersaturated urine at nearly constant supersaturation on **COM** particles in a gel matrix. Here, they used the discontinuous measurement of scattered light intensity by microphotometry to quantify various crystal growth parameters. These experiments to a large extent simulate the physiological conditions in which the pathological urinary crystals develop in vivo [48.134].

48.7.2 Effect of Trace Elements

Analyses of urinary stones showed the presence of more than 20 trace elements, and it is believed that these elements might play an important role in the formation of these stones [48.133]. *Girija* et al. [48.95] studied the effect of Mg, Cd, Zn, and Pb on the crystallization of **COM** at room temperature. There was significant influence of these ions on the process of primary agglomeration of **COM**.

The presence of the elements Mg and Zn, which are known to act as inhibitors of calcium oxalate urinary stones, was found to have less effect on crystal agglomeration and dendritic formation than the presence of the nephrotoxic elements Cd and Pb. Furthermore, Cd and Pb reduced the number of individual crystals and increased the tendency to form agglomerates of **COM** and dendrites of **COD** as seen in Fig. 48.4b. The incorporation of Cd and Pb was found to be high, the amount of incorporation following the order: Pb > Cd > Zn > Mg. The addition of Zn modified the morphology of the crystals from prismatic to rhombohedral (Fig. 48.4c [48.95]). Furthermore, *Petrova* et al. [48.97] crystallized **COM** in gelatin, agar-agar, agarose, and sodium silicate gels and studied the dissolution rates in the presence of Al and Fe. The rate of dissolution was found to increase in the presence of these ions, due to the adsorption of ions on the surface of the crystal, hindering further growth.

48.7.3 Effect of Tartaric and Citric Acids

Marickar and *Koshy* [48.135] crystallized **COM**, **COD**, dicalcium phosphate dihydrate (**DCPD**, brushite, $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$), octacalcium phosphate (**OCP**, $\text{Ca}_8(\text{HPO}_4)_2(\text{PO}_4)_4 \cdot 5\text{H}_2\text{O}$), **HAP**, **MAP**, and magnesium hydrogen phosphate trihydrate (**MHP**, newberyite, $\text{Mg}(\text{PO}_3\text{OH}) \cdot 3(\text{H}_2\text{O})$) by reaction method in silica gel. The effect of known inhibitors of crystallization, viz. tartaric acid, citric acid, and human urine (affected and

unaffected), were studied. Tartaric and citric acid altered the crystal habit and inhibited growth. Urine from patients with stones modified the crystal habit. Normal urine samples produced reduction in the size of the crystals along with change in morphology. It is surmised from these observations that normal urine contains inhibitors of crystallization and that these were absent in the urine of certain patients affected by urinary stones.

48.7.4 Effect of the Extracts of Cereals, Plants, and Fruits

Natarajan et al. [48.99] grew crystals of **COM**, **DCPD**, and **MAP** in silica gel medium using reaction method, incorporating extracts of some cereals, plants, and fruits to screen these materials for their inhibitory role on crystallization of these compounds. Control experiments were carried out simultaneously to compare the growth of crystals without [48.98] and with the extracts. The concentration of the various substances incorporated in the gel was about 5 g/l. The generally expected inhibitory effects are the following:

1. No nucleation to lead to crystal growth (a powdery mass being produced)
2. Reduction in the number and size of the crystals
3. Change in the morphology of the crystals.

By carefully observing the shape, size, and approximate number of crystals obtained and also from the knowledge of their total mass, conclusions were derived regarding the inhibitory or promotive effect of the extracts incorporated. It was observed that the extracts of *Cocos nucifera*, *Citrus limon*, *Lycopersicon esculentum*, *Mimosa pudica*, *Musa sapientum*, *Hordeum vulgare*, *Tribulus terrestris*, and *Policos biflorus* produced very good inhibitory effects on **COM** crystallization. The extracts of *Mentha spicata*, *Raphanus sativus*, and *Vitis vinifera* had no effect on crystal growth. It was also interesting to observe that the extracts of *Borassus flabellifer* and *Ananas comosus* promoted the crystallization, producing larger crystals of **COM** crystals.

Irusan et al. [48.108] studied the effect of the herbal extracts *Phyllanthus niruri* and *Ocimum sanctum* on the crystallization of **DCPD** and found that, in the presence of these herbal additives, there was considerable reduction in the thickness of the crystals and also that the crystals became dendritic in nature. *Freitas* et al. [48.136] have also studied the effect of the aqueous extract of the folk medicinal plant *Phyllanthus niruri* on **COM** crystallization and concluded that the plant extract has an inhibitory effect on crystal

Table 48.4 Effect of cereal, plant, and fruit extracts on the crystallization of some urinary stone components

Cereal/plant/fruit		Effect of extracts on crystallization			Reference
Botanical name	Popular name	COM	DCPD	MAP

growth. Recently, Joshi et al. [48.137] have shown the inhibitory effect of two herbs, viz. *Tribulus terrestris* and *Bergemia liuquolata*, on the growth of COM crystals, in vitro. *Bergemia liuquolata* was found to be a better inhibitor of COM than was *Tribulus terrestris*. They infer that the presence of some macromolecules in these

herbs seems to play an important role in inhibition of COM crystals. It may be pertinent to point out that the particular ingredient of the cereals/plants/fruits responsible for the inhibitory or promotive effect is yet to be identified. The observations of the various experiments described are summarized in Table 48.4.

48.8 Calcium Phosphates

Calcium phosphates are the major constituents of bone and teeth. Dental calculus, bursitis, arthritis etc. are the pathological conditions involving the deposition of calcium phosphate-like minerals. Calcium phosphate may mineralize in various phases, such as HAP, tricalcium phosphate (TCP, whitlockite, $\text{Ca}_3(\text{PO}_4)_2$), OCP, dicalcium phosphate (DCP, monetite), and DCPD, in order of increasing solubility. Investigations on the

Fig. 48.5 Microstructure of a COM stone showing HAP as nidus of about 600 μm in diameter (indicated by an arrow)

nucleation and growth of calcium phosphates such as **DCPD**, **DCP**, **OCF**, **TCP**, and **HAP** have received considerable attention in connection with the formation of metabolic and nonmetabolic stones [48.138–140]. Among these, **DCPD** plays an important role in the formation of caries lesions under acidified conditions. Needles of **DCPD** crystals were reported in the outer layer of calculi [48.141]. It also forms the basis for the nucleation of calcium oxalate crystals.

Tiny crystals of **HAP** sometimes form in and around joints and can cause inflammation around the articular cartilage and periarticular connective tissues. They have been described as a cause of inflammations of the shoulder [48.87]. **HAP** is also a constituent of the urinary calculi and is sometimes found in the nidus of **COM** stones (Fig. 48.5 [48.142]). **HAP** has also been detected in atherosclerotic lesions [48.143].

48.9 Hydroxyapatite (HAP)

Fig. 48.6 Platy crystals of **HAP** grown in silica gel (after [48.144], © IOS) ◀

At present, there is no simple technique to crystallize large single crystals of **HAP** at ambient temperature. The crystal growth of **HAP** at ambient temperature and pressure conditions always yielded crystals of nanometer size. *Ashok* et al. [48.112] reported the crystallization of platy crystals of **HAP**, using single-test-tube diffusion technique in silica gel media at physiological temperature (37 °C). Discs of **HAP** containing platy crystals of size $27 \times 2 \mu\text{m}$ were obtained (Fig. 48.6, [48.112, 144]) using low-temperature crystallization techniques using gels. *Girija* et al. [48.113] also crystallized **HAP** biomimetically on collagen gel to evaluate the biomineralization process.

48.10 Dicalcium Phosphate Dihydrate (DCPD)

There are several reports on the crystallization of **DCPD** in gels [48.109]. Spherulitic **DCP** and **DCPD** of different morphologies which have close resemblance to

those found in pathological joints, stones, and dental calculi were crystallized in silica gel at physiological pH and temperature by *Sivakumar* et al. [48.107]. The crystals grown without any additives had characteristic platy and spherulitic morphology of **DCPD** and **DCP**, respectively (Figs. 48.7, 48.8a). Scanning electron photomicrographs of synthesized spherulitic **DCP** crystals revealed that the crystal consisted of radially arranged aggregation of rectangular rod-like spokes and rectangular platelets (Fig. 48.8b).

Fig. 48.7 Elongated platy crystals of **DCPD** grown in silica gel

48.10.1 Effect of Additives on Crystallization of Calcium Phosphates

The influence of organic and inorganic ionic species (Mg/Ca , Cd , Zn , Pb , $\text{P}_2\text{O}_7^{4-}$, and citrate) on crystal-

lization of DCP, DCPD, and magnesium phosphates have also been studied by Sivakumar et al. in silica gel [48.107, 114]. Incorporation of magnesium ions in the crystallizing medium led to a change in the size and morphology of crystals and the mechanical properties of the crystals (Fig. 48.9).

Even when the concentration of the calcium ions was considerably less than that of the magnesium ions, platy DCPD crystals were found to crystallize along with the MHP and MAP crystals (Fig. 48.10). The hardness of the MHP and MAP crystals increased with increasing calcium ions. The presence of magnesium ions in the crystallizing medium drastically reduced the hardness and also reduced the number of DCPD crystals. The magnesium ions decreased the hardness, whereas lead ions increased the hardness of the DCPD crystals. The incorporation of calcium in MHP and MAP crystals increased the hardness, whereas cadmium reduced the hardness. The presence of pyrophosphate and citrate ionic species in the crystallizing medium did not have any influence on the morphology, microstructure, and lattice parameters of DCP, DCPD, MHP, and MAP crystals. From in vitro crystallization using silica gels, it was concluded that Mg^{2+} , Zn^{2+} , $P_2O_7^{4-}$, and citrate ions inhibit growth of DCP, DCPD, and MAP crystals, whereas Cd^{2+} and Pb^{2+} accelerate the growth of crystals [48.107].

Anee et al. [48.110] studied the effect of Fe^{3+} ions on the crystallization of DCPD at various temperatures (27, 37, and 47 °C) using agarose gel medium. In these experiments, crystallization was inhibited in the absence of Fe^{3+} at 37 and 47 °C. Figure 48.11 shows iron-doped DCPD crystallized by single-diffusion technique at 27 °C. At 47 °C, spherulites of HAP were found to grow in the gel medium along with DCPD crystals. These crystals were of average length 1.33 mm

Fig. 48.8 (a) Spherulitic crystals of DCP and (b) its microstructure

Fig. 48.9 Change in habit of DCPD when crystallized in silica gel with magnesium ions

and breadth of 4.28 μm , forming spherulites of more than 2.7 mm in diameter. Previous studies reported crystallization of needle-like morphology of HAP, of only micro- or nanometer size [48.111, 145, 146]. These studies [48.110] showed that Fe^{3+} played a significant role in the crystallization of phase-pure HAP at physiological pH. Furthermore, this technique provided an easier method to synthesize large crystals of HAP, at a low temperature.

Combined influence of an organic and an inorganic ion (cobalt and malic acid) on crystallization of DCPD

Fig. 48.10a,b Crystals of (a) newberyite (MHP) and (b) struvite (MAP) grown in silica gel

Fig. 48.11 DCPD crystals grown in agarose medium in presence of Fe^{3+}

in agarose gel was reported by Anee et al. [48.105]. Morphological changes were noticed when the growth assay was doped with cobalt and malic acid. Even at very low concentrations, malic acid exerted an influence on crystal morphology, producing elongated crystals. Increase in the malic acid concentration in the crystallization media promoted entry of Co^{2+} into the DCPD crystals. Hence, malic acid is expected to be a mediator for transporting Co^{2+} from the supernatant liquid into the gel where crystallization occurred. However, no crystallization occurred in the presence of malic acid alone. Presence of cobalt promoted crystallization, whereas malic acid modified the morphology of DCPD crystals. The molecules of organic additives can bind specifically to certain crystal planes during growth and modify the morphology of the crystals [48.147]. These types of studies help in understanding the process by which organic molecules control the biomineralization process leading to crystal deposition.

48.10.2 Effect of Some Extracts of Cereals, Plants, and Fruits and Tartaric Acid

Natarajan et al. [48.99] have also grown crystals of DCPD using reactants in silica gel and experimented with extracts of various cereals, plants, and fruits as possible inhibitors, as described in Table 48.4. It is of interest to observe that all the extracts tested, except *Policos biflorus* and *Musa sapientum*, inhibited crystallization of DCPD. The extract of *Policos biflorus* showed a promotive effect, whereas *Musa sapientum* had no effect on the crystal growth. Tartaric acid and tamarind (*Tamarindus indica*) were found to inhibit the

crystallization of DCPD in silica gels, due to the formation of calcium tartrate in preference to DCPD, as reported by Joseph et al. [48.138].

48.10.3 Calcium Hydrogen Phosphate Pentahydrate (Octacalcium Phosphate, OCP)

Iijima and Moriwaki [48.116] crystallized OCP in polyacrylamide gels; their experiments revealed that, in addition to other enamel extracellular matrix proteins, amelogenin nanospores are directly involved in controlling the morphology of crystals during enamel mineralization. Marickar and Koshy [48.135] also reported growth of OCP crystals in silica gel.

48.10.4 Magnesium Ammonium Phosphate Hexahydrate (MAP) and Magnesium Hydrogen Phosphate Trihydrate (MHP)

MAP and MHP are two major crystalline constituents of nonmetabolic or infection-induced urinary stones [48.139, 140]. These stones arise from infection produced by urea-splitting organisms such as *Proteus mirabilis*. The urease-catalyzed hydrolysis of urea generates ammonia, which elevates urine pH and causes precipitation of Mg^{2+} , as struvite. Though surgical treatment gives an immediate relief, it is usually followed by relapse of infection and recurrence of stone formation. The recurrence rate of struvite and newberry stone formation is high compared with other urinary stone constituents [48.148].

MAP and MHP were crystallized through the direct crystallization method in silica gel medium [48.114] as mentioned in Sect. 48.10.1; the presence of Mg/Ca , Zn , $\text{P}_2\text{O}_7^{4-}$, and citrate was found to inhibit the growth of MAP and MHP, whereas Pb and Cd promoted growth.

The effect of the extracts of several cereals, plants, and fruits on the crystallization of MAP was studied by Natarajan et al. [48.99]. As evident from the Table 48.4, all the extracts screened (except *Vitis vinifera*, *Policos biflorus*, *Ananas comosus*, *Hordeum vulgare*, and *Tribulus terrestris*) played inhibitory roles in the growth of MAP crystals. *Hordeum vulgare* and *Tribulus terrestris* promoted, whereas *Vitis vinifera*, *Policos biflorus*, and *Ananas comosus* had no effect on crystallization of MAP.

48.11 Calcium Sulfate

Naturally occurring mineral, gypsum (calcium sulfate dihydrate ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$, CSD)) is one of the rare constituents of urinary stones. Gypsum also finds applications in dentistry and pottery, apart from its major use in the medical field to immobilize broken limbs after the bones have been set. Growth of gypsum crystals in silica

gel has been reported [48.100,101]. Kumareson and Devanarayanan [48.101] crystallized CSD using double-diffusion technique in silica gel and further studied the influence of additives such as citric acid, borax, and barium chloride. It was found that the presence of these additives increased the perfection of the grown crystals.

48.12 Uric Acid and Monosodium Urate Monohydrate

Uric acid ($\text{C}_5\text{H}_4\text{N}_4\text{O}_3$) is the major end-product of purine metabolism (Fig. 48.12). The classic example of a crystal deposition disease is gout. Gout is a very painful inflammatory condition associated with deposition of monosodium urate crystals [48.149] in various tissues of the body. Crystals of uric acid anhydrate and dihydrate as well as its sodium salts have been found in the renal tract, and interstitial tissues of the kidney and its collection ducts. Uric acid anhydrate and dihydrate are often found as a constituent of urinary calculi and have a high incidence in nephrolithiasis resulting in severe kidney damage [48.150, 151]. The solubility of uric acid changes dramatically with pH and, in acidic urine when supersaturated with uric acid, it is deposited as uric acid crystals [48.152]. It is found to occur in pure form or in association with calcium oxalates, HAP, struvite, and sodium and ammonium urates. In addition, it has been suggested that uric acid crystals could act as a support for heterogeneous nucleation of other crystalline species [48.153, 154].

Uric acid is insoluble in alcohol, ether, and most common organic solvents and, owing to its extremely low solubility in water, it would be difficult to prepare a pure specimen because of the large volume of solvent needed. As uric acid has very poor aqueous and organic solubility, it is very difficult to crystallize them in an aqueous medium such as silica gel. Kalkura et al. [48.10] crystallized uric acid dihydrate in TMOS

and silica gels using single- and double-diffusion techniques (Fig. 48.13). In this case, a solution of uric acid in sodium hydroxide was allowed to diffuse into the gel to produce a displacement reaction with dilute HCl inside the gel medium, producing uric acid crystals. These experiments showed that uric acid, which has a low aqueous and organic solubility, can be crystallized in an aqueous medium such as silica gel and in TMOS without the use of bulk solvents.

Monosodium urate monohydrate (MSUM) is the salt of singly ionized state of uric acid, and a component of urinary stones. It has also been identified in articular tissues of patients managed with long-term dialysis [48.155]. The presence of characteristic needle or spherulitic forms of MSUM in synovial fluid and within synovial leukocytes is recognized as a strong indication of the presence of gouty arthritis [48.156]. The synthetic crystals of MSUM were needle shaped, whereas the crystals grown in the presence of serum, synovial fluid, and components thereof closely resembled the morphology of the MSUM crystals present in the articular cartilage in vivo [48.157]. A saturated solution of

Fig. 48.12 Molecular structure of uric acid

Fig. 48.13 Crystals of uric acid grown in TMOS gels

Fig. 48.14 (a) Spherulites of sodium urate monohydrate crystallized in **TMOS** gels, (b) magnified image

sodium urate in the presence of urate seeds at pH greater than 6.0 will form needle-shaped sodium urate crystals.

MSUM, which resembled the crystals found in synovial fluid of gouty patients, has been crystallized fairly easily by *Kalkura et al.* [48.115] without resorting to

any heating of the solutions in a wide range of pH (3–10) using **TMOS** and silica gels compared with the other existing standard method, viz. slow cooling of a NaOH–uric acid solution kept at pH of 8.9 from 60 to 4 °C, as seen in Fig. 48.14 [48.115, 154].

48.13 L-Cystine

Crystallization of cystine ($C_6H_{12}N_2O_4S_2$, Fig. 48.15), a dibasic sulfur-containing amino acid present in the body, results in disorders such as cystinuria and cystinosis. Cystinuria is characterized by excretion of large quantities of the above amino acid in urine. Cystinosis results in the formation of cystine calculi and could

Fig. 48.15 Molecular structure of cystine

even lead to kidney damage. Cystine crystals could also occur in liver, spleen, thyroid glands, bone marrow, and ocular tissues [48.158]. Cystine can act as a seed and favors the crystallization of **MAP** [48.159], a urinary stone constituent with a high degree of recurrence [48.160].

Since cystine has low aqueous and organic solubility, it is difficult to crystallize using conventional methods of gel technique. Earlier, cystine crystallization was carried out in solution by dissolving it in an alkaline solution (ammonia) and then reducing it

Fig. 48.16a–d Different morphologies of crystals of cystine crystallized from silica gels: (a) Bipyramidal (after [48.11], © Springer 1995), (b) hexagonal (after [48.11], © Springer 1995), (c) hollow crystal with a thread passing through it, (d) rectangular crystals

using a weak acid, such as acetic acid. In a novel technique, reported by *Girija et al.* [48.11], cystine was dissolved directly in silica gel and the crystals of cystine appeared without the diffusion of any supernatant solution into the gel medium. Here, acetic acid used for acidifying the silica gel also played the role of the reduction agent to produce crystals.

48.14 L-Tyrosine, Hippuric Acid, and Ciprofloxacin

Some components that are rarely found in urinary stones include L-tyrosine ($C_9H_{11}NO_3$), hippuric acid, and ciprofloxacin ($C_{17}H_{18}FN_3O_3$). Tyrosine is an amino acid present in living organisms. Hippuric acid ($C_6H_5CONHCH_2COOH$) is a colorless crystal obtained from urine of domestic animals and humans [48.162]. It is believed to be a natural regulator of urinary saturation with regard to calcium oxalate crystallization, which is the most frequent chemical constituent of all the urinary stones. Also, hippuric acid is a potential nonlinear optical (NLO) material. Ciprofloxacin is an antibiotic drug used for a wide range of infections. Drugs such as ciprofloxacin and triamterene induce calculi and they, along with many other drug metabolites, represent 1–2% of all renal calculi [48.160]. Ciprofloxacin crystals form rarely in humans. *Ramachandran and Natarajan* [48.111, 117, 163] reported

Single, twinned, and bunched hexagonal, cubic, rectangular, bipyramidal, and hollow morphologies of cystine crystals (Fig. 48.16a–d) were obtained by this technique [48.11, 104]. Cystine crystallized in the presence of ascorbic acid exhibited tetragonal structure and in addition had hourglass-type inclusion in crystals of rectangular morphology [48.161].

the crystal growth of L-tyrosine, hippuric acid, and ciprofloxacin (Fig. 48.17) in silica gel.

48.15 Atherosclerosis and Gallstones

Cardiovascular disease is one of the leading causes of death in humans. Cardiovascular diseases include such conditions as heart attacks, strokes, high blood pressure, and heart failure [48.165]. The main cause of these diseases is atherosclerosis (thickening of the artery due to the fatty deposits which are largely composed of cholesterol). Atherosclerotic plaques normally consist of lipids such as cholesterol, cholesteryl esters, and phospholipids [48.166]. These deposits interfere with normal blood flow and may result either in depriving some areas of adequate blood supply, in the formation of a blood clot or in the rupture of blood vessels.

48.15.1 Crystal Growth in Bile

Crystal growth frequently occurs in bile, usually resulting in the formation of gallstones. Generally, gallstones

Table 48.5 Constituents of gallstones and their relative abundance (%) (after [48.164], © Elsevier 1981)

Anhydrous cholesterol	$C_{27}H_{46}O$	52.3

Artefacts, unidentified material	–	3.3

Fig. 48.18a–c Types of gallbladder stones: (a) cholesterol, (b) pigment, (c) mixed type

vary from patient to patient in number, size, color, and shape, as well as in composition (Fig. 48.18a–c, [48.164, 167]). Cholesterol is the most common constituent but certain calcium salts, notably calcium carbonate, are frequently present (Table 48.5). As cholesterol has low aqueous solubility, it is either solubilized in bile salt micelles or associated with different phospholipids, vesicles or with lipoprotein particles as free cholesterol or as cholesterol fatty-acid esters [48.168].

Bile secreted by the liver becomes supersaturated with cholesterol. Such abnormal bile contains an ex-

cess of cholesterol relative to the solubilizing agents, bile salts, and the phospholipid lecithin [48.169]. The liver, perhaps as a result of genetic programming, produces supersaturated bile by decreased secretion of bile salts or increased secretion of cholesterol, or both. The excess cholesterol precipitates out of the solution as solid monohydrated cholesterol microcrystals [48.170]. The cholesterol microcrystals precipitated from the bile are retained and subsequently aggregate and grow into macroscopic stones (Fig. 48.18a, [48.171]).

A possible explanation for the lack of cholesterol crystallization in some supersaturated bile is that a nucleating factor is required to seed crystal formation. Evidence has been obtained from bile-mixing experiments that gallbladder bile contains a nucleating factor that could be specific to the gallbladder or bile of cholesterol gallstone patients. Nucleation of cholesterol has been recognized as an important step in gallstone formation but few studies have been performed to examine the ability of potential nucleating agents to influence cholesterol crystal formation. Some of the factors which contribute to crystallization in bile may be crystal aggregation, overgrowth, and epitaxy [48.172].

48.15.2 Cholesterol and Related Steroids

Steroids are an important class of chemical compounds found in virtually all forms of plant and animal life. They are also extensively used in the treatment of ailments ranging from coronary insufficiency to endocrine hormone alterations. Cholesterol ($C_{27}H_{46}O$) is one of the most abundant steroids found in the animal kingdom. It is found in brain, nerve tissues, cell membranes, and gallstones. Plant sterols are structurally similar to cholesterol, and β -sitosterol ($C_{29}H_{50}O$) is the most common plant steroid. β -Sitosterol is a constituent of the gallbladder bile and gallstones. Cholesterol is supposed to be the causative agent for coronary heart diseases and gallstones. Cholesterol and similar compounds are the precursors of the steroid hormones, which play vital roles in human metabolism.

Cholesterol crystals are also seen in rheumatoid nodules, tophi, unicameral bone cysts, and even in isolated cholesterol granulomas of the skin [48.173]. When the cholesterol concentration exceeds the solubility limit in the lipid bilayers of micelles, deposition of cholesterol takes place. This leads to nucleation of crystalline cholesterol and subsequently to atherosclerosis and gallstones. The cholesterol has a ring system as illustrated in Fig. 48.19. It consists of three six-membered rings and a five-membered ring. The interesting fea-

Fig. 48.19 Molecular structure of cholesterol ring

ture of the cholesterol crystals is the bilayer nature of its structure, with a molecular arrangement generally similar to that of cholesterol in biological membrane [48.174].

The physicochemical properties of cholesterol are important to its necessary functions on membranes. Many of the features of cholesterol are also found in its physiologically important derivatives. Cholesterol plays a significant role in the synthesis of essential steroids such as bile acids, sex hormones produced in special glands (ovaries, corpus leutum, placenta, and testis), adrenocortical hormones and vitamin D [48.158]. An esterified form of cholesterol plays an important role in atherosclerosis and cholelithiasis. Cholesteryl esters are precursors for the cyclic formation of free cholesterol synthesis. In addition to cholesterol monohydrate, anhydrous form of cholesterol is also present in freshly removed human gallstones, whereas atherosclerotic plaques contain only monohydrated cholesterol [48.103].

Kalkura and Devanarayanan have shown that cholesterol and related steroids such as cholesteryl acetate and β -sitosterol, which has a low aqueous solubility, can be crystallized in an aqueous silica gel medium without cholesterol being precipitated [48.12]. The single-test-tube diffusion method was employed to grow crystals of cholesterol in silica gel medium by solubility reduction technique. Cholesterol and cholesteryl acetate crystals grown in vitro are shown in Fig. 48.20 [48.12]. Cholesterol and β -sitosterol formed anhydrous crystals in the absence of water and monohydrated crystals in the presence of water. Platy and fibrous crystals of cholesterol monohydrate were obtained when crystallized in silica gels. This technique has also been used to study the effect of various solvents and the extracts from medicinal plants on the crystallization [48.102, 175]. The extracts of some Indian medicinal plants, viz. *Commiphora mughul*, *Aegle marmeleos*, *Cynoden dactylon*, *Musa paradisiaca*, *Polygala javana*, *Alphinia officinarum*, and *Solafoium* were used as additives to study their effect on the crystallization behavior of cholesterol. It was found that many of these herbs have an inhibitory effect on crystallization in terms of nucleation, crystal size or habit modification. Trace elements also seem to play an important role in the pathological mineralization of gallstones [48.176–178].

Fig. 48.20 (a) Cholesterol and (b) cholesteryl acetate crystallized in silica gel

Fig. 48.21a,b Cholic acid crystallized in (a) silica, (b) TMOS gels (after [48.54], © Akademie Verlag 1997)

48.15.3 Cholic Acid

Cholic acid ($C_{24}H_{40}O_5$) is one of the bile acids and is responsible for many physiological functions, including promotion of lipid diffusion through intestinal mucosa, resorption of drugs, vitamins, and hormones, activation/inhibition of various enzyme reactions, and excretion of cholesterol [48.175]. Steroidal cholic acid and its derivatives can serve as host molecules to form inclusion compounds with a wide variety of organic substances. Cholic acid is also a promising candidate to be used as a building block in biomimetic/molecular recognition chemistry and in the construction of extended, preorganized molecular structures [48.179]. Kalkura et al. reported the crystallization of cholic acid in silica and TMOS gels. Crystals grew with different morphologies, and Liesegang rings were also seen in some cases. The grown crystals were found to be monohydrate in form (Fig. 48.21a,b, [48.54]). Since the bile salts have the ability to form inclusion compounds with a variety of molecules, these studies will be helpful in understanding the role played by cholic acid and its derivatives in cholesterol crystallization in gallbladder.

48.16 Crystallization of Hormones: Progesterone and Testosterone

Steroid hormones are derived from cholesterol, and a very small amount of these exerts potent physiological effects. Progesterone ($C_{21}H_{30}O_2$) is a naturally occurring mammalian hormone. It is known as the hormone of pregnancy because of its importance just prior to and during the gestation period. It is secreted by corpus luteum (material which surrounds the egg). The main functions of progesterone are the following:

1. Preparation of the uterine endometrium for the implantation of fertilized ovum
2. Maintenance of uterus during/after pregnancy
3. Inhibition of spontaneous contraction of the uterus
4. Participation in the development of breast
5. Inhibition of ovulation [48.180].

Progesterone is an important intermediate in biosynthesis of adrenocortical and gonadal steroid hormones. It also forms the basis for oral contraceptive agents.

Testosterone ($C_{19}H_{28}O_2$) belongs to a class of compounds called androgens. Androgens are responsible for the development of the male sex organs. Testosterone is the most active androgen and it is the functioning hormone found in the testes, ovary, and adrenal cortex. This most potent male sex hormone is isolated from testicular tissue and spermatic vein blood. The important function of this group is in the development

Fig. 48.23 Crystals of testosterone as grown in silica gel with crystals in the supernatant solution due to the reverse diffusion (arrow)

of masculine sexual characteristics such as deepening of voice, growth of a beard, and distribution of pubic hair. Their structure is similar to that of the female sex hormones, viz. estrogens [48.181]. Crystallization of the above hormones was carried out by Kalkura and Devanarayanan [48.12–14] by modifying the techniques of crystallization of steroids in gels. Crystals were obtained (Fig. 48.22a,b) when there was a slow diffusion of water into the gel medium containing sex hormones (progesterone and testosterone) in liquid phase. This suggests a possible mechanism for the growth of crystals. Water, while diffusing through the gel, supersaturates the sex hormone which is in a liquid phase in the gel medium, leading to nucleation of the crystals and their subsequent growth. In addition, crystals also appeared in the supernatant solution, due to the slow reverse diffusion of the precipitating solution from the gel medium into the supernatant solution, leading to the supersaturation of the hormones (Fig. 48.23).

Fig. 48.22a,b Crystals of progesterone grown inside (a) silica gel, (b) crystallized in the supernatant due to reverse diffusion of the precipitating solvent

48.17 Pancreatitis

The pancreas in all mammalian species is an important gland located in the upper abdomen behind and below the stomach. The pancreas has both exocrine and

endocrine functions. Inflammation of the pancreas is known as pancreatitis. Chronic pancreatitis is a continuing inflammatory disease of the pancreas characterized

Fig. 48.24 Surgically removed pancreatic stones

by irreversible morphological changes that typically cause pain and permanent loss of pancreatic function. Initially, pain dominates, soon followed by the clinical complication of calcification, leading to stone formation (pancreatic calculi), in the main duct (Fig. 48.24). Biological fluids are generally supersaturated with respect to calcium salts such as oxalates in urine, phosphates in saliva, and carbonates in bile or pancreatic juice. It might become harmful if continuous crystal growth is allowed, leading to the formation of stones. Inhi-

Fig. 48.25 Scanning electron micrograph of a bipyramidal calcite crystal

bition of stones is mainly done by protein inhibitors. In the pancreas, the stone formation is inhibited by a 144-amino-acid glycoprotein (15.5 kDa). However, the role of the pancreatic stone protein (PSP), called lithostathine, is controversial and is expected to contribute to the stone formation.

Studies on the composition of pancreatic stones using x-ray diffraction methods revealed calcium carbonate as the primary constituent [48.182, 183]. In addition, traces of nickel and fatty acids, organic matrix with desquamated epithelium, fibrin mucoid substances, and protein have also been reported [48.182]. Recent studies on pancreatic stones using x-ray diffraction, Fourier-transform infrared (FTIR) spectroscopy, and electron paramagnetic resonance (EPR) by *Narasimhulu et al.* [48.184] support the view that lithostathine has a role in the formation of pancreatic stones.

48.17.1 Calcium Carbonate

Calcium carbonate (CaCO_3) exists in three polymorphic forms: aragonite, vaterite, and calcite [48.185]. Calcite occurs as a biomineral and happens to be the major constituent of pancreatic calculi [48.186] and also a constituent of gallbladder and urinary stones [48.156, 159].

Gel method of crystallization has been used extensively to study calcium carbonate crystals to elucidate the biomineralization process. Double-diffusion technique using silica gel has been employed to study the effect of divalent cations Ba^{2+} , Sr^{2+} , Co^{2+} , and Mn^{2+} , in small concentrations (50, 200, and 600 ppm) [48.82]. Furthermore, calcite has also been crystallized using double-diffusion technique with polyacrylamide hydrogels incorporating carboxylate groups [48.93]. *Imai et al.* have crystallized porous aragonite crystals in silica gel [48.94]. *Ramachandran et al.* [48.91] have crystallized CaCO_3 in silica gel (Fig. 48.25) and studied the thermal parameters by photoacoustic method.

48.18 Conclusions

The *in vivo* processes leading to formation and growth of crystals in biological fluids are influenced by various factors which are very complex and not yet fully understood. Gel is the most suitable medium to study biomineralization because of its viscous nature, providing simulation of synovial fluid, cartilage, and other biological fluids where crystallization occurs. An ideal *in vitro* crystallization technique which mimics or sim-

ulates exactly the *in vivo* mineralization processes is yet to be developed. As described in this chapter, crystallization in gels is an ideal technique to study the pathological biomineralization *in vitro*, as this method provides a fairly simple technique which closely resembles crystallization *in vivo*. Furthermore, it can be extended to understand problems concerned with biological, medical, and geological aspects of biominerals.

Almost all major and minor constituents of pathological deposits which are responsible for diseases, such as atherosclerosis, gallstones, urinary stones, etc., can be crystallized in various gel media. Gel method of crystallization is also an ideal method to study the effect on crystallization of electric and magnetic fields, various drugs, herbal extracts, and the epitaxial relationship between the constituents in order to understand the anti- and pronucleating factors, which will help in finding factors that help in dissolution of pathological crystal deposits under physiological conditions. Once stones are formed in our body system, they rarely disappear and always grow in size. The factors responsible for this

are not clearly understood. Hence, suitable solvents and inhibitors could be applied to crystals in gel medium to determine the conditions under which already formed crystals can be dissolved, modified or inhibited from the viewpoint of devising new treatments and means to control crystal deposition diseases.

Intense research is going on into the pathogenesis and etiology of crystal deposition diseases. Medical treatment of crystal deposition diseases and prevention from further attacks are still at the experimental stage. Extensive research work is still needed to understand the factors that influence the formation and growth of various crystals in biological fluids.

49. Crystal Growth and Ion Exchange in Titanium Silicates

Aaron J. Celestian, John B. Parise, Abraham Clearfield

In situ experiments, whether carried out in-house or at synchrotron sources, can provide valuable information on the nucleation and subsequent growth of crystals and on the mechanism of growth as well as mechanisms of phase changes and ion-exchange phenomena. This chapter describes the types of x-ray detectors, in situ cells, and detectors used in such studies. The procedures are illustrated by a study of the preparation of a tunnel-structured sodium titanium silicate, the partially niobium framework phase, and the mechanism of ion exchange as revealed by time-resolved x-ray data.

49.1 X-Ray Methods

Hydrothermal techniques for the synthesis of new materials and for crystal growth have been used extensively since the 1950s, and this has increased substantially over the last decade. The use of in situ studies in many cases is desirable since the data collection and analysis

methods do not disrupt the chemical reaction or process. In the ex situ hydrothermal process, especially when new materials are the goal, the experimentalist usually has control over the time/temperature/pressure conditions and reactant ratios of the synthesis. What is

missing in these *ex situ* processes is knowledge of what takes place as the reaction proceeds. It is possible that the phase(s) formed at elevated temperatures may revert to a more stable phase on cooling. Furthermore, several phase transformations, or metastable intermediates, may occur during the synthesis procedure that would otherwise go undetected in a typical *cook-and-look* experiment. Nucleation and crystal growth, mechanisms of phase changes, and ion-exchange processes are readily studied using *in situ* x-ray diffraction as the major experimental tool [49.1–3]. If the reaction is relatively slow and the resolution required is moderate, the *in situ* study can be carried out in an in-house x-ray facility or at a neutron facility. New detectors and more powerful x-ray and neutron sources are enabling new experimental techniques that allow routine data collection from *in situ* experiments. Compared with conventional sealed-tube x-ray sources, synchrotron radiation is 10^4 – 10^{12} times brighter. At the advanced photon source (APS), Argonne National Laboratory and the newly renovated facility at Brookhaven National Laboratory, National Synchrotron Light Source (NSLS) x-ray powder patterns can be recorded in seconds and with excellent resolution. In what follows, we will describe the types of facilities and provide several examples of how *in situ* studies are performed at synchrotron and neutron user facilities.

There are compromises involved in the collection and interpretation of time-resolved data. The data quality is affected chiefly by the poorer signal-to-noise discrimination, compared with data collected over longer time frames and high-quality *ex situ* data. However, by combining data collected in a *static* manner, on materials representing the beginning and end or the reaction pathway, for example, with time-resolved data, a more complete picture of the mechanism emerges; for example structural models of the kinetics of zeolite synthesis [49.4–6], ion exchange in their various cation-exchanged forms [49.5, 7, 8], in their dehydrated and hydrated states [49.9, 10], and with and without sorbents, are important to rationalizing their mode of operation. Monitoring these structural changes *in situ* and as a function of time allows the mechanism of transformation to be followed. Several case studies involving this approach are given below.

The quality and types of data required to uncover mechanisms depends on the information being sought. The optimization of synthetic conditions only requires identification of the phases and the pressure–temperature–composition conditions over which they

are stable, and many of these can be carried out in the laboratory setting, particularly since the wider availability of area detectors. Powder diffraction data suitable for Rietveld refinement require:

1. Access to brighter x-ray beams at second- and third-generation synchrotron storage rings
2. Versatile high-pressure/temperature and hydrothermal cells designs.

49.1.1 X-Rays and Diffraction Theory

A crystal may be defined as a solid composed of atoms, ions or molecules arranged in a pattern that is periodic in three-dimensional space. The smallest repeating pattern containing all elements and symmetry operations is termed the *unit cell*, and is constructed by three non-coplanar vectors **a**, **b**, **c**, where *a*, *b*, and *c* are the axial lengths of the unit cell, and three angles α , β , γ , where α , β , and γ are the angles between the axes. It is convenient to focus on the geometry of the periodic array. The crystal is then represented as a three-dimensional array of points, each of which has identical surroundings. There exist 14 such lattices, the Bravais lattices, that describe the geometry of crystals. The lattices are infinite in extent and it is possible to construct many sets of parallel planes that pass through the points. The perpendicular distance between any set of such planes is known as the *d*-spacing.

When a beam of monochromatic x-rays is passed through a crystal, diffraction occurs because the wavelength of the x-rays and the distances between atoms, or the sets of planes, are of the same order of magnitude. Diffraction only occurs when the waves being diffracted constructively interfere, and therefore not all *d*-spacing diffraction occurs at the same time. The Bragg equation defines the conditions for diffraction to occur

$$\sin \theta = \frac{n\lambda}{2d}, \quad (49.1)$$

where λ is the x-ray wavelength, θ is the angle of diffraction, and *n* is an integer, which for our purposes may be set to unity. From knowledge of the *d*-spacings it is possible to obtain the values of the unit cell constants. The orientation of a plane in space relative to an axial system may be given in terms of the intercepts of the plane with respect to the axes, or the vector from the origin of the axial system that is perpendicular to the plane. This latter distance is *d* and the intercepts are designated by *hkl*, where *hkl*, are integers that are the reciprocals of the intercepts; for example, if the plane

cuts the a -axis at $\frac{1}{2}a$ then

$$h = \frac{a}{\frac{1}{2}a} = 2.$$

Similarly, k and ℓ are the reciprocals of the intercepts along the b - and c -axis, respectively. There are six axial systems by which unit cells and lattices are described, or seven if we separate trigonal from hexagonal. For each axial system there is an equation relating d with hkl . For the cubic system there is only one unknown as all the unit cell dimensions are equal and the angles are all 90° , then

$$d = \frac{a}{[h^2 + k^2 + \ell^2]^{1/2}}. \quad (49.2)$$

In single-crystal studies it is possible to align each set of parallel planes at their respective Bragg angle to the x-ray beam and record all the d -spacings in three-dimensional space. For in situ synthesis studies this method would be time consuming, and most starting materials used in hydrothermal crystallization experiments are not single crystals, but rather solutions, gels or powders. It is advantageous to use the powder diffraction method to record a large number of d -spacings in one or two dimensions quickly.

The powder method is predicated on the fact that the powder will have an equal number of crystallites in all possible orientations to the x-ray beam, and all diffraction from the sets of d -spacings will be generated simultaneously [49.12]. The angle between the incident beam and the diffracted beam is always 2θ (Fig. 49.1). The detector travels about a circle of fixed radius with the sample at the center of the circle. The x-ray powder diffraction pattern (XRPD) is recorded as the diffracted intensities as a function of 2θ , and is a one-dimensional pattern. For complex structures or mixtures, the diffracted intensities may

Fig. 49.1 Bragg reflection from a set of lattice planes showing that the angle between the incident beam and the reflected beam is always 2θ

overlap, and extracting the intensities of overlapping features becomes increasingly difficult with increasing number of crystalline phases. Therefore the resolving power of the diffractometer becomes an important feature in planning in situ studies. Resolution afforded by synchrotron-based diffraction is much greater than that of in-house powder diffraction techniques. The breadth of an x-ray diffracted peak is measured as the width of the peak at half-height, designated the full-width at half-maximum (FWHM). For medium-resolution powder diffractometer at a synchrotron storage ring the FWHM is $\approx 0.01^\circ$, as compared with 0.1 – 0.5° for the K_α doublet of Cu radiation from an in-house powder diffractometer. Another point to consider is that x-ray diffraction features generally broaden with increasing 2θ values, so that overlap of peaks at high 2θ values also increases.

X-ray scattering arises from the interaction of electrons with the electromagnetic field of the collimated and coherent x-ray beam. As an element's atomic number increase, so does the total number electrons around the atom, and as the number of electrons of the atom

Fig. 49.2 Variation of the atomic scattering factor as a function of $\sin \theta / \lambda$ (after [49.11])

increases, so does the total x-ray scattering power. As a consequence, distinguishing between the scattering power of near neighbors in the periodic table, such as Al and Si, is often difficult because their electron configurations are similar. Also, the atomic scattering factors are angle dependent and fall off with increasing $\sin \theta$, as shown in Fig. 49.2 [49.11]. This dependence decreases the intensities of high-angle reflections. All these factors of x-ray diffraction require the use of high-intensity, well-collimated, narrow-beam radiation available at synchrotron sources. Nevertheless, in-house studies have the advantage of unlimited access where preliminary experimentation data collection may be obtained. The results from in-house data are valuable for determining experimental design, temperature ranges for synthesis, and synthesis times to optimize time spent at remote beam facilities, where access to the most desirable and well-conditioned x-ray and neutron beams is limited.

49.1.2 Neutron Diffraction Theory

Neutrons primarily interact with nuclei of atoms, leading to scattering and diffraction phenomena. According to the de Broglie equation, a beam of particles of mass M and velocity v generates a plane wave of length

$$\lambda = \frac{h}{Mv}, \quad (49.3)$$

where λ is the generated wavelength, v is the velocity, M is the mass of neutron, and h is Planck's constant. At a velocity of 4 km/s,

$$\begin{aligned} \lambda &= \frac{6.625 \times 10^{-27} \text{ g cm}^2/\text{s}}{1.67 \times 10^{-24} \text{ g} \times 4 \times 10^5 \text{ cm/s}} \\ &= 0.992 \times 10^{-8} \text{ cm}. \end{aligned}$$

This simple calculation shows that it is possible to have neutrons whose associated wavelengths are in the range to diffract from crystals or to be scattered by amorphous materials. The characteristics of neutrons provide certain advantages not obtainable with x-rays:

1. The coherent neutron scattering length (b) analogous to the x-ray atomic scattering factors for elements, does not increase with atomic number but fluctuates from element to element, and can be zero [49.13]. Thus, scattering from light elements may be as intense as that from heavy elements.
2. As a consequence of the nature of atomic scattering lengths the differences in scattering of neighboring

elements in the periodic may differ greatly, making it easy to distinguish one from the other. Isotopes also have different scattering lengths, making it possible to distinguish H from D, for example.

3. Because the nuclei are point scatterers, the value of the scattering factor (more properly, the scattering length factor) does not change with increasing values of θ . As a result, the intensity of diffracted radiation does not decrease with increased θ as is the case for x-rays.
4. Many materials exhibit low absorption values for neutrons. This fact allows the use of thicker walled vessels for high-temperature/pressure studies. Further elements (vanadium), or alloys (Ti-Zr) with $b = 0$, are exceedingly useful as null-scattering sample containers. There is no equivalent to this application for x-ray studies, where even amorphous glass adds considerable parasitic scattering to the powder diffraction pattern.
5. Magnetic behavior arises from the presence of unpaired electrons in atoms. Because neutrons possess a magnetic dipole moment, they interact with unpaired electrons. This gives rise to an additional scattering effect that results in the appearance of weak peaks in the diffraction pattern. These extra peaks can be indexed as a superlattice of the x-ray lattice and reveals the magnetic ordering of the unpaired electrons. Thus neutron diffraction can be utilized to study ferro-, ferri-, and antiferromagnetic phenomena not readily accessible to x-ray methodology.

Neutron beams can be obtained from nuclear (steady-state) reactors, where they are typically monochromated by means of curved germanium or silicon crystals (Fig. 49.3).

A second method of neutron generation is through a process termed *spallation*. A heavy-metal target, such as uranium, mercury or tungsten, is bombarded with 450 MeV protons in short uniform bursts which separate the neutrons from the target nucleus. The released neutrons are at high kinetic energy levels and must be thermalized, moderated or cooled (slowed) to be in the 0.2–5.0 Å wavelength range for suitable diffraction studies. This is accomplished by bringing epithermal neutrons into thermal equilibrium with hydrogen-rich moderators such as polyethylene and liquid methane that reduce the velocity of the neutrons. Hydrogen, being about the same mass as the neutron, is most efficient for this process. Because of the high flux of this neutron beam and its range of neutron energies, it is advanta-

geous to use the energy-dispersive method (Fig. 49.3). The Spallation Neutron Source at Oak Ridge National Laboratory uses a time-of-flight methodology. The sample is held at the center of a large ring (source-to-sample distance is 20 m) with banks of detectors held at specific angles to the incident beam, $\pm 30^\circ$, $\pm 90^\circ$, and $\pm 120^\circ$. Use of multiple detector banks increases the total collected intensities, which is necessary because the neutron beam seldom interacts with the sample. In the time-of-flight method, the time for a diffracted beam to reach the detector is measured. Combining the Bragg equation (49.1) in the form of d and substituting for λ the value given by the de Broglie equation

yields

$$d = \frac{n\lambda}{2 \sin \theta} = \frac{ht}{2ML \cdot \sin \theta}, \quad (49.4)$$

where $v = L/t$. Here we utilize the definition of velocity as length L divided by time. Because h , O , M , and L are fixed quantities the d -spacing is proportional to time. The larger the d -spacing, the longer the time for the diffracted radiation to reach the detector. Thus the powder pattern plot of I versus time inverts the normal order of the powder pattern. The smallest d -spacings are recorded at short times and the largest d -spacing is the last peak in the pattern.

Fig. 49.3a-c Comparison of typical geometries for (a) a laboratory-based x-ray source, and for powder diffractometers found at (b) reactor and (c) spallation neutron sources. In (a) the incident x-ray beam of characteristic radiation is selected by the use of a filter (e.g., Ni filter for Cu- K_α radiation) while at a steady-state (reactor) source a single-crystal monochromator selects the desired, narrow, wavelength range from the Maxwellian distribution of neutron energies emerging from the reactor. The scattering from the sample is detected in a position-sensitive detector. In (a), at a spallation (pulsed) neutron source the energies of the neutrons scattered at fixed 2θ are determined according to their time of flight along the flight path relative to the origin of the neutron pulse. This is analogous to the use of energy-dispersive x-ray techniques (see text)

49.2 Equipment for Time-Resolved Experiments

49.2.1 In-House X-Ray Sources

For time-resolved studies the experimenter needs to record a large number of powder diffraction patterns rapidly to capture time-dependent chemical reactions, and therefore a high-intensity source of x-rays is required. A standard sealed-tube x-ray tube may provide a power of 2 kW or 40 mA at 50 kV. Special sealed tubes may be rated as high as 3 kW. The power limit is controlled by the rate at which heat can be conducted away from the anode, and x-ray intensities are directly proportional to the power. About 98% of the energy of a sealed tube is converted to heat, which would soon melt the target unless otherwise cooled. Therefore a constant stream of cold water flows across the back of the anode to conduct the heat away. Sealed-tube x-ray intensities may also be increased by the use of optical fibers. Each fiber consists of a large number of hollow glass capillaries. These capillaries act as waveguides in which the x-rays undergo total reflection from the capillary surfaces and are led to the sample with little loss of intensity.

For more powerful in-house units a rotating-anode generator may be used. In a rotating-anode x-ray generator, the anode is rotated rapidly to always supply a relatively cool metal target for the bombarding

electrons. The anode is connected to a shaft that rotates through vacuum-tight seals in the tube housing. Such units come in two power models: 12 and 18 kW. Some of the new models of rotating anodes approach the x-ray flux observed at second-generation synchrotrons.

49.2.2 Synchrotron Radiation Sources

Synchrotron radiation [49.14] is produced by the acceleration of electrons moving at near the speed of light. The charged particles move in circular orbits within an evacuated chamber termed a *storage ring*. Magnetic fields are used to alter the trajectory of the particles, and this acceleration causes them to radiate energy tangential to the ring. This radiation is then made available to the experimenter via a beamline pipe containing suitable optical components under vacuum. Compared with conventional sealed-tube sources, synchrotron radiation has a flux 10^4 – 10^{12} times brighter. Other advantages of synchrotron radiation are the broad spectral range produced and small radiation divergence, which have the advantage of wavelength selection (typically 0.4 and 1.5 Å at a bending magnet), narrow beam collimation (typically 0.01–0.6 mm), and very low beam divergence.

49.3 Detectors

To obtain a diffraction pattern suitable for structure refinement from in situ diffraction studies, a large portion of the powder pattern must be recorded in a short period of time. Typically monochromatic radiation is used with a detector such as an image plate, position-sensitive detectors, or charge-coupled device (CCD) or using energy-dispersive radiation and a multichannel analyzer. Only the most common types of detectors are discussed below.

49.3.1 Image Plates

Image plates (IP) consist of a thick layer of x-ray-sensitive phosphor on an optically transparent backing. When the x-rays strike the plate, the phosphor grains ionize. The released electrons are trapped at F-centers, which are point defects of the phosphor solid. The plate is then scanned with a small-diameter laser beam that liberates the trapped electrons, which recombine with

the ions from which they were liberated. This transition produces light that is collected in a photomultiplier that amplifies the signal. The amount of light emitted is proportional to the x-ray intensity. Any residual image can be erased by exposing the film to a light source and reused, and the IP is usually read and erased online during the experiment.

The main advantage of using an IP for data collection is the size. The IP represents one of the largest detectors for the collection of diffracted x-ray intensities, with sizes up to and exceeding 34.5 cm. Using a large detector allows data to be collected to approximately 0.8 Å depending on wavelength choice and sample-detector distance. Another advantage of using this type of area detector is that the entire Debye–Scherrer ring can be collected. During in situ crystallization studies, the material may not form in abundance to produce smooth diffraction rings. These rings will often appear spotty and incomplete con-

tributing to the problems associated with small cells that produce small quantities of crystallites. An area detector can overcome this problem as it collects data in two-dimensional space as opposed to point detectors and position-sensitive detectors. The disadvantage of **IP** detectors is the readout time. The **IP** must be digitally scanned and then erased before the next exposure can begin. The process of reading and erasing can take up to 2.5 min, during which time no data is being collected from the experiment. Although this *gap* in data collection appears to be problematic, the advantages of obtaining high-resolution diffraction data in one exposure outweigh those disadvantages.

49.3.2 Charge-Coupled Devices

A charge-coupled device (**CCD**) is simply a semiconductor chip where one side of the chip is subdivided into rectangular sections (pixels) that are approximately 10 μm on edge. Between the x-rays and the **CCD** are a phosphor and a photodiode that convert the incoming light into electrons. Depending on where the light strikes the phosphor, the electrons build in number and are trapped in the rectangular pixel on the **CCD** semiconductor surface. After a complete exposure, the **CCD** is then read using analogue-to-digital conversion, which counts the amount of electrons on each pixel, where the number of electrons is proportional to the original light intensity. In this process, it is possible to have rapid data collection and readout time with little delay between exposures.

However, there are caveats to using a **CCD** for x-ray diffraction studies. For example, if a pixel fills with electrons before the exposure is over, those excess electrons will *spill* into the surrounding wells. This can cause problems when trying to read the detector after x-ray exposure, and may be visible on the processed image as a vertical, or horizontal, streak across the entire image. Another problem is that most **CCD** chips are quite small, typical ranging in size from 512 \times 512 to 2048 \times 2048 pixels. Therefore, such small chips are made usable by having a large phosphor front plate, \approx 15 cm in size, and a fiber-optic taper that reduces the image down to the **CCD** chip, which is \approx 2 cm in size. Naturally, information will be lost during the image size reduction, and care must also be taken to remove the distortion in the fiber-optic taper prior to data reduction. The construction of larger **CCD** chips will eventually lead to the removal of the fiber-optic taper and thus produce a distortion-free raw image.

49.3.3 Position-Sensitive Detectors (PSD)

A **PSD** is a proportional counter that is position sensitive. The proportional counter consists of a tube filled with a noble gas such as xenon. A thin tungsten wire runs down the center of the tube and is positively charged. A thin window of low-absorbing glass allows the x-ray photons to enter the tube and ionize the xenon, which releases a cloud of electrons. The released electrons are drawn to the positively charged wire, giving rise to a charge pulse. The size of the pulse is proportional to the energy of the incident photon, which allows x-rays of different wavelengths to be distinguished. In a **PSD**, the wire can be long and curved to coincide with the diffractometer circle. The **PSD** is placed so as to intercept any x-rays diffracted by the sample within the angular range of the wire. The x-ray beam strikes the wire at particular 2θ values dictated by diffraction from the powder sample. The time of travel taken for the pulse to reach the end of the tungsten wire fixes the position or 2θ value. A multichannel analyzer is able to sort out all the times and amplitudes into digital form and the output is that of a conventional powder pattern.

PSDs are available in a range of sizes starting from $\approx 4^\circ$ to 120° in 2θ . All the reflections within this range are recorded simultaneously. By choosing a smaller wavelength it is possible to record the entire usable range of diffraction data in a single exposure using a 30° or 60° **PSD**. The advantage of a **PSD** is their readout time, which far exceeds that of the **IP**, and allows near-continuous diffraction patterns to be collected without interruption. Most **PSDs** are linear, thus only one-dimensional diffraction data can be obtained, which may result in diffracted intensities being missed because of incomplete Debye–Scherrer rings from non-ideal powder samples.

49.3.4 Energy-Dispersive Detectors

At a synchrotron source, a broad range of x-ray energies can be produced. The peak of the energy distribution depends on the ring characteristics, including the energy of the charged particles within the ring and the strength of the magnets used to bend particles around the ring. A beam of well-defined energy is produced for monochromatic studies by intercepting this *white* radiation with a single-crystal monochromator. Alternatively, if the powder sample is held at a specific angle and the incident beam contains a broad spectrum of wavelengths, a particular set of planes of fixed *d*-spacing will diffract only that wavelength that satisfies Bragg's

law for that value of d . Thus, all the different wavelengths which satisfy this condition for all the planes in the sample will enter the detector and be sorted out by the multichannel analyzer. The entire pattern may be recorded in less than 1 min. The main advantage of using white radiation is the intensity of the beam. The high flux, and hard x-rays, have a higher penetration depth and can pass steel environmental cells. One disadvantage of the energy-dispersive detector is that its peak resolution is poorer compared with monochromatic beams.

49.3.5 Silicon Strip Detector

A new detector, offered by Brucker Corporation, contains 192 strips of silicon which act as 192 individual detectors. This results in an almost 200 times increase in intensity. This detector together with fiber optics may open many opportunities for in situ studies in-house.

49.3.6 Other Considerations

There are several disadvantages when area detectors are used without collimation, some of which are due to the nondiscriminating nature of both imaging plates and charge-coupled devices. The synchrotron beam inevitably excites fluorescence within the hutch and care must be taken to shield these devices from stray radiation. The difficulty in designing slits for these devices also decreases the signal-to-noise discrimination since scattering from sample containers, or environmental chambers, often contaminates the pattern. Although this

can be eliminated using subtraction [49.15, 16], another possibility when powder averaging is not a problem and angular resolution can be relaxed ($\Gamma \approx 0.03^\circ$), is to use an energy-discriminating PSD fitted with a slit. While most commercial PSDs operate in the so-called *streaming mode*, proportional counting and energy discrimination are possible with these devices.

The highest possible time resolution is afforded by energy-dispersive diffraction. Since the whole pattern is recorded at once, this resolution is determined by the brightness of the beam and the readout time of the multichannel analyzer. Quantitative interpretation of crystal structure is hampered by systematic errors such as energy-dependent absorption corrections, absorption edges, and definition of the intensity versus energy curve. Reliable results have been obtained, however, and the software and method to enable structure determination using the Rietveld method are now well established [49.16, 17]. The energy-dispersive x-ray technique does have distinct advantages. The experiment allows for straightforward collimation and data collection at fixed angles, which makes it easier to discriminate parasitic scattering from sample containers.

In general, for phase identification and determination of unit cell parameters, energy-dispersive x-ray diffraction data are suitable and offer distinct advantages in terms of spatial and time resolution. In those cases where accurate determination of structural parameters is the objective, monochromatic data are preferred. Many beamlines are capable of changing between these two modes of operation, and a description of such a setup is given in two recent reviews [49.18, 19].

49.4 Software

Collection of either x-ray or neutron diffraction data with ever-increasing time resolution, as is envisioned at third-generation synchrotrons, will inevitably lead to data glut. While visual inspection, to identify the appearance of one phase or the disappearance of another, may be sufficient in some studies, an unbiased method which can be automated to provide some real-time feedback on the course of a reaction is desirable. Such a method might provide information on systematic errors as well as the appearance of new phases and the disappearance of others. It should also provide visual queues to allow the choice of a manageable number (3–5) of diffraction patterns to analyze out of the hundreds collected. One example in situ XRD

investigation, ion exchange in porous titanium silicates, is discussed below and employs iterative target transform factor analysis (ITTFa) [49.20], an unbiased mathematical treatment of the diffraction data that looks for changes as a function of time. From this processing, kinetic information and clues as to which patterns to use first for Rietveld refinement were obtained. Problems and questions such as which patterns to explore, whether measurable changes are occurring, and determining if the reaction has completed are vital for efficiently managing the ever-increasing quantities of data. Also general structure analysis software (GSAS), Fullprof+winplotr, and Power3D are freeware that are capable of handling large sets

of one-dimensional diffraction data. Since new software is continuously appearing on the Internet, the authors cannot give a detailed software overview. How-

ever, the CCP14 website contains a vast collection of software that is useful in interpreting time-resolved data [49.21].

49.5 Types of In Situ Cells

Fig. 49.4 Beamline geometry suitable for time-resolved synchrotron powder diffraction in monochromatic mode. A double-crystal monochromator (M) is used to select the incident energy that is focused on the sample, capillary or flat plate holder (SAC), and recorded on a position-sensitive detector (PSD), image plate (IP) or charge-coupled device (CCD). An incident-beam monitor (IC) is needed to normalize the data to the same relative intensity scale because the synchrotron beam decays with time (after [49.22]) ►

A schematic diagram of the beamline geometry suitable for time-resolved synchrotron diffraction is shown in Fig. 49.4 [49.22]. For in situ studies where structural studies are to be performed monochromatic radiation is preferred. The beam passes through an incident beam monitor ion chamber (IC) to record the intensity of the incident beam during the entire run. Monitoring the incident beam is necessary because the synchrotron beam decays with time, and therefore the total intensity of the diffraction pattern also decreases with time. If a synchrotron runs in the so-called top-off injection mode, where electrons are continuously supplied to the storage ring, an IC is still required because the storage ring is usually not topped off to a constant value. The monitored data is then used to normalize the data to the same intensity scale.

Our own interests are twofold: to grow crystals from gels that possess ion-exchange properties and then to study the mechanism of ion exchange. The crystal growth is done to temperatures of 150–250 °C but the ion exchange may be carried out at room temperature and at ≈ 60 °C. Two different reaction cells are used for these purposes. The crystal growth experiments are carried out hydrothermally, requiring elevated pressures. A quartz capillary reaction cell introduced by Norby [49.23] is shown in Fig. 49.5. The capillary is closed at one end (A) and is held in place with a Swagelok fitting (B) mounted on a modified goniometer head. Heating can be effected by heating plates placed above and below the capillary tube so as not to obstruct the path of the x-ray beam, or by using an air blower heater. A small amount of gel to be crystallized is placed into

the capillary and fixed into the Swagelok fitting, and a pressure of N₂ is applied through the fitting. The detector is an imaging plate of which only a portion is exposed to the x-rays. This is done by placing two lead shields (D) over the IP, exposing a portion of the plate to the x-rays. At the end of each cycle the IP film is moved to expose a fresh surface. A cycle consisted of

Fig. 49.5 The capillary reaction cell and translating imaging-plate detection system as used at the NSLS

a 60 s exposure and erasure, and exposing a new IP surface required 1.5 min for data processing or 2.5 min per cycle. Recent improvements in the storage ring at the NSLS Brookhaven National Laboratory and detection system have now reduced the time per cycle to seconds. This cell has been widely used by many investigators [49.3].

49.5.1 SECeRTS Cell

A somewhat different type of cell was used for the ion-exchange studies, and is also easily adaptable to synthesis studies. The design of a small environmental cell for real-time studies (SECeRTS) [49.24] is shown in Fig. 49.6. A quartz, or sapphire, capillary (0.3–1 mm OD) tube (A), open at both ends is mounted in a Swagelock tee (B) using a Vespel ferrule. A pressure can be applied, through the connected tube (C), to the surface of the reaction mixture in the capillary. For titration synthesis studies, injection takes place through a 0.3 mm quartz capillary (A) that goes through the tee and into the 1 mm capillary. This 0.3 mm capillary

is mounted between a Swagelock elbow and tee with Vespel ferrules, all of which are mounted on a modified goniometer head (E). Injection under pressure through the elbow (A) is possible via a gas-chromatography syringe (not shown) mounted on an aluminum holder. A screw connected to the piston of the syringe ensures pressurization. By turning the screw, the piston is depressed and a controlled volume can be injected into the 1 mm capillary through the 0.3 mm capillary. Alternatively, the position of the sample capillary (A) can be plugged, and the assembly can be extended to expose the injection capillary location in the x-ray beam. Ports D and C then become the supply and exhaust lines, respectively, for flow-through ion-exchange experiments or solid/gas-phase reactions.

It is important to note that completely sealed capillaries pose a significant risk to experimentalists and equipment. The pressure generated during hydrothermal reactions is difficult to control in small-diameter capillaries, and they could burst at any time during the heating of the cell. Having an open end where an overpressure of inert gas is applied is a safety feature to

Fig. 49.6a,b View of the capillary-type small environmental cell for real-time studies (SECeRTS). (a) In situ hydrothermal titration cell and (b) simplified quartz or sapphire hydrothermal cell (courtesy of John Parise and coworkers, Stony Brook)

prevent the cell from exploding while still maintaining hydrothermal conditions.

49.5.2 Polyimide Environmental Cell

The polyimide environmental cell (PEC) was designed to alleviate the problems and safety issues associated with quartz capillaries and gas-driven solutions. Initially designed for flow-through experiments [49.26], the PEC is easily adaptable to in situ synthesis experiments by simply sealing one end and applying an overpressure of nitrogen to the other. Polyimide tubing was chosen to replace the quartz/sapphire capillaries based on multiple criteria. The tubing is flexible, thin walled, and x-ray transparent (within the radiation range of 0.1–1.54 Å) in the wide-angle region. Controlled solution flow through a larger-inner-diameter tube is easier to maintain and reproduce. Tube breakage is no longer a problem during sample loading or during the experiment because of the flexibility of polyimide. Tube transparency in the wide-angle region ($2\theta > 2^\circ$) means only x-ray scattering from the sample and solution contributes, with no parasitic scattering from the polyimide cell, to the diffraction patterns in that region. Thin walls (typically < 0.01 mm for a 0.8 mm OD tube) allows more sample in the beam and increases peak-to-background ratios.

49.5.3 High-Pressure Cells

High-pressure cells commonly in use can often be adapted with slight modification for use in in situ studies at a synchrotron. For example, the large-volume high-pressure device originally designed for diamond growth (DIA) has been successfully interfaced to a synchrotron at the Photon Factory, Japan [49.13]. Similar installations were constructed at the NSLS Brookhaven, the advanced photon source (APS) Argonne, and at Deutsches Elektronen Synchrotron (DESY) in Germany. They are utilized in the study of materials at high pressure and temperature using mainly energy-dispersive diffraction. In some cases the use of monochromatic radiation together with the IP was more effective. An example is the partitioning of Fe in a mixture of olivine and the β -phase (Fe,Mg)₂SiO₄ [49.16] using an IP and monochromatic radiation resulted in considerably better time resolution, and the mechanism of the transformation from the olivine structure to the spinel structure was observed [49.27].

Other sample cells, such as furnaces and diamond-anvil cells, are also easily transferred. Similarly, steel

hydrothermal reaction vessels can be transferred from the laboratory to the synchrotron.

49.5.4 Hydrothermal Steel Autoclave-Type Cell

Evans et al. [49.25] introduced a hydrothermal autoclave reaction vessel (Fig. 49.7) that has been extensively used in many studies [49.28]. The cell consists of a modified Parr reaction vessel (25 ml) with a section of the wall milled down to a thickness of 0.4 mm. This thinner portion of the wall permits transmission of white x-radiation and has a maximum operating temperature of 230 °C. Higher operating temperature is possible with thicker-walled cells. However they require the focusing optics available at a third-generation source [49.29]. Attached to the top of the cell is a head consisting of a pressure transducer, a safety relief valve, and an injection reservoir (2 ml). This reservoir consists of a remotely placed gate valve that permits injection of a second solution into the cell at

Fig. 49.7 The hydrothermal autoclave-type reaction cell due to Evans et al. [49.25]. Walls are milled down to allow x-ray transmission while permitting a maximum operating temperature of 300 °C

controlled time and temperature conditions. Temperature control of the cell is done via a resistance-heated aluminum block and is monitored with K-type thermocouples in contact with the outside of the reaction vessel.

49.5.5 Neutron Diffraction Cell

For neutron diffraction studies, a vanadium (V) tube is used instead of polyimide, quartz or sapphire. The coherent neutron scattering length of vanadium is

small, $b = -0.5$ fm, compared with that of oxygen, which is 5.8 fm, making it an ideal sample container since it contributes primarily to the incoherent background and not to the Bragg diffraction in a powder pattern (Fig. 49.3b). Also, the V-tube is much larger in diameter (6.5 mm) to allow more powder to be used (Fig. 49.8). The low absorption cross-section of neutrons allows the use of larger samples, which perhaps will be more representative of the situation when using titanium silicate (TS) (see below) in the field.

Fig. 49.8 Diagram of vanadium can assembly for flow-through studies

49.6 In-Situ Studies of Titanium Silicates (Na-TS) with Sitinakite Topology

49.6.1 Introduction to the Problem

Large quantities of nuclear waste were generated as a byproduct of the US nuclear weapons programs. The waste is held in large, underground steel tanks at both the Hanford and Savannah River sites. A search for efficient, cost-effective methods of removing cesium, strontium, and actinides from the waste solutions is an ongoing project of the Department of Energy. A sodium titanium silicate (Na-TS) was found to be highly selective for Cs^+ and Sr^{2+} in moderately alkaline solutions. When the Na-TS material was immersed in the highly alkaline wastes its selectivity for Cs^+ was low, but in a partially Nb-substituted form (Na-NbTS) the material was highly effective at removing Cs^+ [49.30]. Several problems are attendant to the use of these titanium silicates for separation of high-level waste.

The nuclear waste is a highly basic solution containing 1–3 M NaOH. It also has high sodium ion concentration, 5–7 M, and contains a variety of other ionic species. The ions that are the highest γ -emitters are the highly radioactive ^{137}Cs and ^{90}Sr , with 30 years half-lives. In addition, small amounts of Pu and Np also need to be removed from the mass of waste. This high-level waste (HLW) would be sealed in a special glass and stored in steel tanks below ground. The remaining low-level waste (LLW) would be taken up in a grout and stored aboveground.

The questions are: what are the structural and/or chemical properties of sodium titanium silicate that display such high uptake of Cs^+ in neutral to mildly basic solution, but not in the waste solutions? Also, what effect does the substitution of Nb for some Ti have on the increased selectivity toward Cs^+ ? In short, what is the origin of the high ion selectivity in these compounds? In addition, the hydrothermal syntheses by which these titanium silicates are prepared are often accompanied by the appearance of impurity phases. What are these impurities, and how can they be eliminated from the synthesis [49.5, 6]?

49.6.2 Synthesis and Structure of Sodium Titanium Silicate (Na-TS)

The ideal composition of this titanosilicate is $\text{Na}_2\text{Ti}_2\text{O}_3\text{SiO}_4 \cdot 2\text{H}_2\text{O}$. However, hydrolysis occurs in water to yield a composition of $\text{Na}_{1.64}\text{H}_{0.36}\text{Ti}_2\text{O}_3\text{SiO}_4 \cdot 1.8\text{H}_2\text{O}$ [49.31]. The crystal structure of the sodium

ion phase and the partially exchanged Cs^+ phase were determined from powder x-ray studies [49.31].

The crystals are tetragonal, with $a = 7.8082(2) \text{ \AA}$, $c = 11.9735(4) \text{ \AA}$, space group $P4_2/mcm$, and $Z = 4$. The titanium atoms occur in clusters of four grouped about a 4_2 axis, two up and two down, rotated by 90° . Each titanium is octahedrally coordinated, sharing edges in such a way that an inner core or four oxygens and four Ti atoms form a distorted cubane-like structure (Fig. 49.9).

These cubane-type structures are bridged to each other through silicate groups along the a - and b -axis directions. The titanium–oxygen clusters are 7.81 \AA apart in both the a - and b -axis directions, with the Si atoms at $c = \frac{1}{4}, \frac{3}{4}$. The c -axis is $\approx 12 \text{ \AA}$ long, which is twice the distance from the center of one cubane-like cluster to its neighbor in the c -axis direction. Two views of the framework are shown in Figs. 49.10 and 49.11. The net result of this framework arrangement is that one-dimensional tunnels are formed along the c -axis di-

Fig. 49.9 A portion of the titanosilicate structure showing the cluster of four titanium–oxygen octahedra sharing edges to form the cubane-like Ti_4O_4 group. The oxygens within the cubane group are each bonded to a proton making them hydroxo groups. The Ti atoms are light brown, oxygens are dark brown, and hydrogens are black

Fig. 49.10 Top view (down the c -axis) of sodium titanium silicate showing the clusters of four TiO_6 octahedra bridged by silicate groups. The tunnels are filled with Na^+ and water molecules. The Na^+ on top of the tetrahedra symbolizes the Na^+ ions sandwiched between silicate groups within the framework. Refer to Fig. 49.11 for color legend

Fig. 49.11 Polyhedral representation of Na-TS structure as viewed down the a -axis, showing the hexagonal-shaped framework cavities in which half the Na^+ reside. The water molecules reside within the 8MR tunnels

rection. Perpendicular to the tunnels are vacancies in the faces, or four sides, of the tunnels. These cavities are large enough to enclose sodium ions. Four silicate oxygens bond to the sodium ion at a distance of $2.414(5) \text{ \AA}$ (Fig. 49.11). The sodium ion coordination is completed by bonding to two water molecules in the tunnels at a Na-O bond distance of $2.765(1) \text{ \AA}$. Half the sodium ions are thus accounted for in the framework sites as there are sodiums in each face at $c = 0, \frac{1}{2}$ over one c -axis cell length for a total of four out of the eight required per unit cell. The remaining sodium ions reside within the tunnels along with the water molecules. As a historical note, these compounds were originally misnamed as crystalline silico titanate (CST). However, they are silicates, so their preferred nomenclature is as a titanium silicate M-TS, where M is the exchangeable ion.

The Na-O bond distances within the tunnels are longer than the sum of the ionic radii (2.42 \AA) [49.32] at $2.76(1) \text{ \AA}$. This bond distance measurement was made with only 64% of the sodium ion sites occupied. The deficiency of sodium arises from hydrolysis during washing so that the actual formula was $\text{Na}_{1.64}\text{H}_{0.36}\text{Ti}_2\text{O}_3(\text{SiO}_4) \cdot 1.8\text{H}_2\text{O}$. Because of the deficiency of Na^+ , the sodium ion positions were found to be disordered with partial occupancy by water molecules. It is possible to obtain the fully occupied sodium phase by not washing the product of the hydrothermal reaction with water, or washing with strong NaNO_3 solution.

On exchanging Cs^+ for Na^+ by a flow-through procedure in near-neutral CsCl solution, a composition of $\text{Na}_{1.49}\text{Cs}_{0.2}\text{H}_{0.31}\text{Ti}_2\text{O}_3\text{SiO}_4 \cdot \text{H}_2\text{O}$ was obtained [49.31]. The Cs^+ occupied two positions within the large tunnel. Site one (Cs1) is located at the center of the eight-membered ring (8MR) window at $\frac{1}{4}c, \frac{3}{4}c$, and Cs2 is located at approximately $0.13c$ and $0.63c$ off from the 8MR window. Cs1 has eightfold bonding coordination to eight oxygens of the framework, four above and four below the Cs, with bond lengths of 3.18 \AA . Cs2 has fourfold bonding coordination to the framework oxygens and twofold coordination to the interstitial water with bond lengths of 3.06 and 2.95 \AA , respectively. The bulk of the Cs^+ was in site 1 and about 20% in site 2.

49.6.3 Synthesis Problems and In Situ Hydrothermal Study

A problem arose in the actual sol-gel synthesis of the Na-TS crystals. Often an impurity began to form

that on further investigation was determined to be a sodium titanium silicate of composition $\text{Na}_2\text{TiSiO}_5$ referred to as sodium titanium oxide silicate (STOS). In ex situ hydrothermal studies it was found that the amount of STOS in the mixture increased with the alkalinity of the starting gel. In contrast, the conditions for favorable Na-TS formation required a lower Na_2O content as well as lower pH. Based on this ex situ study we prepared two gels, one designed to yield pure STOS and the other to yield pure Na-TS [49.6]. The gel composition for Na-TS had the composition $1.0\text{TiO}_2 : 1.98\text{SiO}_2 : 6.77\text{Na}_2\text{O} : 218\text{H}_2\text{O}$. In situ experiments were carried out at the Brookhaven synchrotron. The source of Ti was titanium isopropoxide, to which was added NaOH and silica dissolved in NaOH. The apparatus used is that shown in Fig. 49.5, and the results are provided in Fig. 49.12. Figure 49.12 shows a three-dimensional plot of the x-ray diffraction pattern as a function of time during the TS gel heating. As can be seen from the figure, the process starts with the formation of a phase having a broad peak at about $9.5\text{--}10\text{ \AA}$. This phase was identified as sodium nonatitanate (SNT) $\text{Na}_4\text{Ti}_9\text{O}_{20}$, a semicrystalline compound that is highly selective for Sr^{2+} in alkaline solution [49.33, 34]. It starts forming at an

early stage of reaction, as confirmed by the collection of x-ray powder diffraction patterns of the dried starting gel. The intensity of the (001) SNT reflection does not change as the reaction progresses until the growth of the TS phase begins. The process of transformation of the SNT phase to the TS phase started after 1 h of constant heating at 220°C , with rapid decrease of the intensity of the SNT peaks and in-growth of the TS peaks (Fig. 49.13). The whole process of transformation lasted approximately 45 min. During the period following the transformation to TS, no significant changes occurred, except a minor increase in the TS peak intensities. No other phases were observed in this experiment.

Interestingly the highly alkaline base gel in ex situ experiments also crystallized as the SNT phase first, as shown in Fig. 49.14. After about 12 h at 200°C it is converted to the highly crystalline STOS phase in an additional 15 h. Thus, it appears that in gels of different composition and alkalinity the SNT phase forms initially. Then the sodium silicate that remains converts the SNT phase to the Na-TS phase at low sodium content and moderate alkalinity, while at higher sodium content and higher alkalinity the STOS phase prevails. Several avenues of synthesis are now open. The SNT phase is

Fig. 49.12 Time-resolved x-ray powder diffraction spectra of SNT-TS transformation for the gel with composition $1.0\text{TiO}_2 : 1.98\text{SiO}_2 : 6.77\text{Na}_2\text{O} : 218\text{H}_2\text{O}$. Powder patterns are collected in 2.5 min intervals

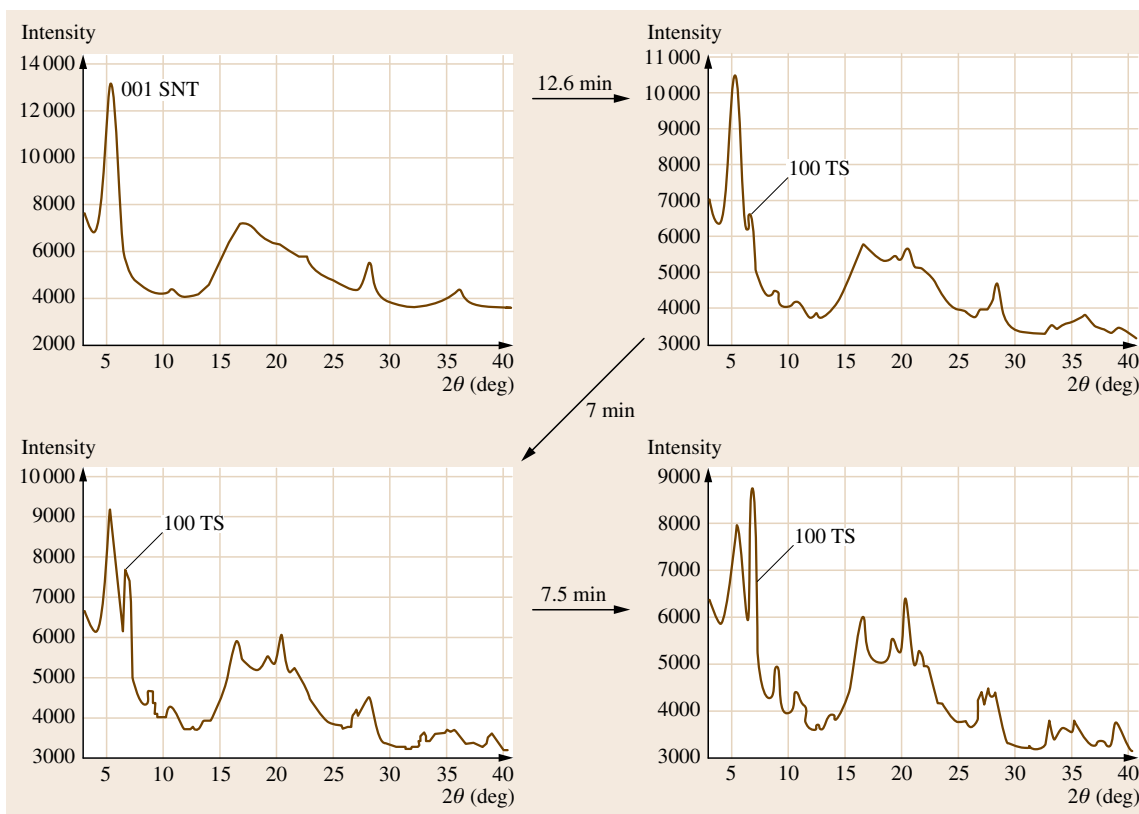

Fig. 49.13 XRD patterns of SNT (upper right) and its transformation with time to the TS phase at 220 °C. The pattern in the upper right-hand corner is that of pure SNT

readily prepared from a mixture of titanium isopropoxide and NaOH. By adding the correct balance of silica dissolved in NaOH it is possible to avoid the presence of the STOS impurity. Furthermore, by proper control of the reaction it may be possible to prepare a mixture of Na-TS and SNT, such as to remove Cs^+ and Sr^{2+} in a simple one-step process.

49.6.4 Ion Exchange of Cs^+ into Na-TS

The ion-exchange experiments were carried out at the X7B beamline of the National Synchrotron Light Source. The open-capillary SECRéTS cell was used (Fig. 49.6). Exchange of Cs^+ from a 1 mM solution of CsCl was used for the Na-TS phase and a 10 μM solution for the exchange with the protonated H-TS phase. The lower-concentration solution was necessary to slow the rate of exchange to fully observe the changes occurring in the H-TS phase. Diffracted intensities were recorded on a MAR345 imaging plate. Each diffraction

pattern was collected for 1 min with a 1.5 min lag time to read and erase the IP.

As the Cs^+ was exchanged for Na^+ in Na-TS, the unit cell volume increased from 728.8 to 732.4 \AA^3 [49.26]. The unit cell parameters a and b showed a continuous increase from 7.8060(1) to 7.8435(1) \AA and the c -axis decreased from 11.9599(2) to 11.9054(4) \AA . The ion exchange occurred in two steps. The first step, from minutes 0 to 245, involved occupancy of Cs^+ in the Cs2 site to a fractional occupancy of 0.116(5). Simultaneous with the increased occupancy of site Cs2, the water site OW2 began to decrease in occupancy (Fig. 49.15). Figure 49.15 also shows a concomitant loss of Na^+ as the Cs^+ was taken up. The second step of the ion exchange from minutes 245 to 375 was initiated when site OW2 had zero occupancy (minute 245) and involved the rapid filling of site Cs1 (Fig. 49.15). During minutes 245 to 275 the occupancy of Cs2 increases and reaches a maximum occupancy of 0.136(7). The maximum occupancy for

Fig. 49.14 Dynamic XRD spectra of the evolution of the STOS phase obtained in ex situ experiments from the gel of composition $1.0\text{TiO}_2 : 1.98\text{SiO}_2 : 10.53\text{Na}_2\text{O} : 218\text{H}_2\text{O}$, $T = 200^\circ\text{C}$

Fig. 49.16a,b Ball-and-stick representation of a portion of the proton phase $\text{H}_2\text{Ti}_2\text{O}_3(\text{SiO}_4)_4 \cdot 1.5\text{H}_2\text{O}$ as viewed down the c -axis, showing the hydrogen bonding scheme between the acid proton and the water molecules O₅ and water–water and water–framework oxygens (a) and a polyhedral representation showing the elliptical nature of the tunnel along the c -axis direction and the new unit cell (bold line) along the diagonals of the Na-TS unit cell ◀

the Cs1 site was 0.25. These values yield a formula of $\text{Na}_{1.06}\text{Cs}_{0.26}\text{H}_{0.68}\text{Ti}_2\text{O}_3\text{SiO}_4 \cdot \text{H}_2\text{O}$. The proton content was due to hydrolysis and the amount was calculated to balance the charge. Almost all the Na^+ in the tunnel was lost to hydrolysis and exchange for Cs^+ . The maximum amount, or fraction, of Cs^+ that can be exchanged into the TS phase is 0.5. This has been shown by titration with CsOH [49.35, 36] and from ex situ structural studies. The Cs^+ is too large to occupy the Na1 framework sites and for the same reason can only occupy half the tunnel sites.

49.6.5 Cesium Ion Exchange into H-TS

There is a major difference between Cs^+ ion-exchange pathways in Na-TS and H-TS. Replacement of the sodium ions by protons is accompanied by a space group change from $P4_2/mcm$ to $P4_2/mbc$ and unit cell dimensions [49.35, 37] of $a, b = 11.039(5) \text{ \AA}$, $c = 11.880(5) \text{ \AA}$. The protons are covalently bonded to the cubane oxygens and hydrogen bond to water molecules in the tunnel. The reason for the change is that the a, b axes transition from 7.806 \AA to the larger value (actually the ab square diagonal), and the symmetrical eight-membered ring perimeter of the tunnel is distorted into an elliptical shape (Fig. 49.16). The ratio of the length to the width of the tunnel is now 1.2. A very fast exchange of Cs^+ into the Cs2 site (six-coordinate site) occurs in the first 10 min of exchange, as shown in Fig. 49.17 [49.5]. The structure then reverts back to the $P4_2/mcm$ space group, restoring the symmetrical tunnel shape. At this point the Cs1 site begins to fill up, occurring simultaneously with the space group transformation. The diffraction patterns contained both phases to the end of the experiment. After 20 min, both sites continued to fill until a final composition of $\text{Cs}_{0.36}\text{H}_{1.64}\text{Ti}_2\text{O}_3\text{SiO}_4$. Since complete filling with Cs^+ would have the Cs fractional content of 0.5, the exchange was 72% complete. This value is quite high considering how dilute the exchange solution was initially.

49.6.6 Sodium Niobium Titanosilicate (Nb-TS)

Niobium forms a solid solution with the sodium titanium silicate Na-TS up to about 25% replacement of Ti by Nb. This phase, of ideal composition $\text{Na}_{1.5}\text{Ti}_{1.5}\text{Nb}_{0.5}\text{O}_3\text{SiO}_4 \cdot 2\text{H}_2\text{O}$, has a higher selectivity for Cs^+ in highly basic solutions containing higher levels of Na^+ than does the non-niobium-containing phase. As a first step in determining why this phase possesses such a high selectivity for Cs^+ , the crystal structure of the cesium ion phase was determined [49.38]. The presence of Nb^{5+} is statistically distributed over the titanium sites and reduces the sodium ion occupancy in the tunnel by half. However, in this phase considerable hydrolysis occurs, so that the tunnel contains almost no Na^+ but only water [49.38]. This lack of competing ions in the tunnel changes the coordination number of Cs^+ in the tunnel to 12. That is, there are eight water molecules per unit cell in the tunnel and two Cs^+ . With no Na^+ in the tunnel all the water molecules bond to Cs^+ at a bond distance of 3.13 Å, compared with 3.26 Å for the eight framework oxygens. This increase in coordination number apparently greatly decreases the free energy of exchange as Cs^+ changes from a weak coordination in the aqueous phase to very high coordination within the tunnel.

49.6.7 In Situ Synthesis of Na-NbTS

The preparation of the niobium Na-TS phase is often plagued with an impurity that is probably a polymeric Keggin ion, referred to as Na-IPX. A gel was prepared from Nb_2O_5 , titanium isopropoxide, silicon tetraethoxide, and 3.3 M NaOH. The ratio of constituents was $1.0\text{TiO}_2:0.167\text{Nb}_2\text{O}_5:1.33\text{SiO}_2:6.9\text{Na}_2\text{O}:228\text{H}_2\text{O}$. This gel was heated in a Teflon-lined pressure vessel at 200 °C for 4 days. The resultant Na-NbTS was highly crystalline but contained a small amount of Na-IPX. A similar gel was prepared for the in situ study at the X7B beamline of the National Synchrotron Light Source, Brookhaven National Laboratory. The wavelength used was 0.9223 Å and an external N_2 gas pressure of 250 psi was applied to the sapphire capillary. A sapphire capillary was used because silica is solubilized at the high-pH conditions of the starting gel and would weaken the integrity of the capillary. The gel was heated to 210 °C in 2 min and x-ray diffraction patterns were recorded every 2.5 min.

The initial pattern of the gel exhibited two broad peaks centered at 17.6° and 24.5° in 2θ . The results

Fig. 49.17 In situ time-resolved x-ray diffraction showing the onset of Cs^+ for H^+ ion exchange to be a site-selective process. The Cs2 position first filled to $\approx 20\%$. After Cs2 filled, Cs1 began to fill the channels along the [001] direction and completed at $\approx 20\%$. The mechanism of exchange is seen as an opening of the [001] channels as Cs2 bonds to the Ti—O—Si polyhedra linkages, allowing Cs1 to fill the center of the eight-membered ring

are shown in Fig. 49.18. Between minutes 0 and 65, the broad features began to diminish. Simultaneously a third broad feature developed at $\approx 5.1^\circ 2\theta$, associated with the crystalline ordering of the Na-IPX phase. From minutes 65 to 75, the reflections from the impurity phase began to increase in intensity, with the strongest peak arising from the broad feature at $\approx 5.1^\circ$ (Fig. 49.18). From minute 75 to the end of the experiment, the impurity phase ceased to increase in intensity as the Na-NbTS phase began to crystallize. The Na-NbTS phase continued to grow for 25 min, and after 100 min no further changes in the diffraction pattern were observed.

Unit cell refinements of Na-TS during crystallization showed an initial increase in the a - and b -axes and a decrease in the c -axis in a brief span of 5 min from minute 75 to 80 (Fig. 49.19). After the initial anomalous expansion, the unit cell volume and unit cell parameters increased until the end of the experiment. The unit cell volume increased from 743 to 745 Å³ from minute 75 to the completion of the run. By slight adjustments of the gel composition it was possible to achieve phase purity by elimination of Na-IPX formation, as illustrated by this in situ study.

49.6.8 In Situ Ion Exchange of Cesium Ion Exchange in Na-NbTS

The time-resolved x-ray patterns collected during Cs^+/Na^+ exchange [49.26] are shown in Fig. 49.20.

Refinements of the cell parameters during the exchange process indicated that no structural transformation had occurred during exchange. The space group remained $P4_2/mcm$ and the eight-membered ring (8MR) of the tunnel remained circular. The changes in unit cell dimensions as exchange proceeded are provided in Fig. 49.21. The a - and b -axes increased from 7.8470(5) Å to 7.8535(5) Å while the c -axis decreased from 11.980(1) Å to 11.963(1) Å. However, after an initial increase in unit cell volume due to the more rapid increase in the a , b parameters, the unit cell volume was very nearly the same at the end of the Cs^+ uptake as for the original Na-NbTS. This exchange process was interpreted as continuous filling of sites Cs1 and Cs2 with little structural distortion, which contrasts with the exchange studies in the Na-TS and H-TS forms. The break in the curves of Fig. 49.21 was due to filling of the storage ring when no x-rays were available.

49.6.9 Cesium Ion Exchange into H-NbTS

A major difference between the Na-NbTS phase and the Na-TS phase is that no space group change occurred when the Na^+ was replaced by H^+ . The Ti/Nb fractional occupancies refined to 0.77(3) and 0.23(3), respectively, and were fixed to a ratio of 0.75/0.25 based on previous compositional studies [49.38, 39]. No Na^+ was detected by microprobe analysis. Thus, the formula, both by elemental analysis and x-ray refinement, was fixed at $\text{H}_{1.5}\text{Nb}_{0.5}\text{Ti}_{1.5}\text{SiO}_7 \cdot 2\text{H}_2\text{O}$. The proton parameters could not be determined by the x-ray refinement, but it was assumed that they are covalently bonded to the cubane oxygen sites in a similar fashion as seen in the H-TS structure. The water molecules were also distributed in crystallographic sites analogous to Na-TS. Water (OW1) is located near the walls of the 8MR and the intersection of the 6MR, i.e., those cavities where the Na^+ in the framework is located. Water (OW2) is located near the center of the channel along the c -axis, but not on the 4_2 -screw special position. This offset from the screw axis results in the partial occupancy of the OW2 site where its maximal allowed occupancy is 1/2 due to positional disorder.

No structural change was observed in the exchange reaction since all peaks in the diffraction patterns could be indexed on the basis of a single unit cell (Fig. 49.22). The unit cell dimensions initially increased to minute 70, then showed a continuous volume decrease as the a - and b -axes decreased from 7.837(1) to 7.828(1) Å and the c -axis decreased from 11.921(2) to 11.912(2) Å (Fig. 49.23). Rietveld refinement of the

Fig. 49.19 Results of the unit cell refinements of Na-NbTS during crystallization. Initial cell lengths were $a, b = 7.844(2) \text{ \AA}$, $c = 12.073(4) \text{ \AA}$ and final cell lengths were $a, b = 7.857(2) \text{ \AA}$, $c = 12.067(4) \text{ \AA}$ ►

occupancies of the sites populated by Cs^+ and water indicated that ion exchange occurred in two distinct steps (Fig. 49.24). The first occurred from minutes 0 to 197.5 and involved a gradual increase in Cs^+ uptake from 0 to 0.115(6) fractional occupancy at site 1. After the initial Cs^+ uptake, at minute 197.5, H_2O at site OW2 decreased in fractional occupancy from 0.51 to 0.24(3) within 1 min, amounting to slightly more than 0.5 mol H_2O . From minute 200 to the end of the experiment, the fractional occupancy of H_2O at site OW2 remained constant at 0.24(3). The second step of the exchange begins at minute 197.5, during which the Cs^+ uptake increased to 0.339(7) fractional occupancy at the end of the experiment (700 min). The

final formula as obtained from the x-ray data was $\text{H}_{1.33}\text{Cs}_{0.17}\text{Nb}_{0.5}\text{Ti}_{1.5}\text{SiO}_7 \cdot 1.5\text{H}_2\text{O}$.

49.7 Discussion of In Situ Studies

49.7.1 Synthesis of Na-TS and Na-NbTS

Both the Na-TS and Na-NbTS are formed in a very narrow window of gel composition and alkalinity. An excess of silica relative to titanium is necessary to form Na-TS, generally a 2 : 1 ratio. The critical factor in crystallizing a pure TS compound is the

amount and concentration of NaOH in the initial gel. At high molar ratios and concentrations of NaOH, substantial amounts of STOS are obtained. At a concentration of 3.3 M and a ratio of 6.67Na₂O : 1.0TiO₂ a pure Na-TS phase is obtained. However, even with higher ratios and concentrations of NaOH, sodium nonatitanate is found to form first and then is converted to STOS, Na₂TiSiO₅, a synthetic analogue of the mineral natisite. Since the nonatitanate has a high affinity for Sr²⁺ in alkaline solution [49.40, 41], it may be possible to provide a combination of Na-TS and the nonatitanate to remove much of the high-level waste, ¹³⁷Cs and ⁹⁰Sr, from weapons-type nuclear waste with a combination of Na-TS and SNT. Time-resolved synthesis experiments and optimized synthesis procedures can be used to tailor the Na-TS : SNT ratios for a specified removal capacity

Fig. 49.21 Results of the unit cell refinements for data collected during Cs⁺ exchange into Na-NbTS. Unit cell lengths changed from $a, b = 7.8470(5) \text{ \AA}$, $c = 11.980(1) \text{ \AA}$ at minute 0 to $a, b = 7.8535(5) \text{ \AA}$, $c = 11.963(1) \text{ \AA}$ at minute 355.5. The gap in data is when no x-ray beam was available. Error bars are smaller than plot points ◀

Fig. 49.22 Zoomed 3-D time-resolved XRD display for the Cs⁺ exchange into H-NbTS experiment. No impurity phases were present in the diffraction patterns. Diffraction patterns are highlighted (black) every 25 min. Optimization of beam path flight tube resulted in an increase of overall intensity near minute 625

of ^{137}Cs and ^{90}Sr , respectively, without waste of ion-exchange product.

Addition of Nb to the Na-TS reactant mix suppresses the formation of SNT but tends to form Na-IPX [49.42] as an impurity phase. A systematic study is required to determine which conditions give rise to the impurity phase to prevent its occurrence. The broad feature at $2\theta = 24.5^\circ$ in the in situ study of Na-NbTS may result from scattering by amorphous solids that are formed by hydrolysis of the alkoxides during heating to the temperature of the reactant mix. In the case of the gels prepared for synthesis of Na-TS, H_2O_2 was added so all the oxides dissolved in basic solution. The lack of solubility of TiO_2 in alkaline solution may have been responsible for the absence of any crystallization in the first 60 min of the in situ study for Na-NbTS.

49.7.2 Exchange Mechanisms

The results of Cs^+ exchange into H-NbTS indicated that the Cs1 site was the only site filled by Cs^+ . The uptake of Cs^+ in this exchanger was slow relative to exchange in H-TS. Only 0.115 fractional occupancy was achieved in the first 200 min of exchange into H-NbTS. This represents just 0.23 Cs^+ on average per unit cell, compared with an exchange capacity of two Cs^+ per unit cell. There are four water molecules per unit cell, and half of them are lost when Cs^+ has an occupancy of 0.23. After this occupancy, site Cs1 continues to increase in occupancy. This is a significantly different uptake pathway than any other TS, or NbTS, phase where the filling of one Cs site resulted in structural transition allowing a second Cs site occupancy. One might expect that, as the Cs^+ enters the tunnel, a proton coordinately bonded to a cubane oxygen would form a hydronium ion and leave the unit cell. Thus, for each Cs^+ exchanged, a water molecule as a hydronium ion would leave the solid phase. This evidently does not occur in the H-NbTS phase. Rather it might be speculated that the proton follows a hopping mechanism, traversing from lattice oxygen to water to lattice oxygen. As the Cs^+ diffuses into a unit cell the protons leave that unit cell to maintain charge balance. At the surface, the proton hops to a water molecule on the interface of the unit cell, and then leaves the solid phase.

The exchange of Cs^+ into the H-TS and H-NbTS involves different mechanisms. In H-TS there is a rapid uptake of Cs^+ into the Cs2 site. Only when sufficient cesium is present in this site does the 8MR change from its elliptical shape, with length-to-width ratio $L:S = 1.53$, to the circular geometry with $L:S = 1$. Thereafter

Fig. 49.23 Changes in unit cell parameters of the H-NbTS structure as Cs^+ exchanged for H^+ . The two-step process is seen between minutes 0–200 and 200–700. Unit cell lengths at minute 0 were $a, b = 7.837(1) \text{ \AA}$, $c = 11.919(3) \text{ \AA}$, and at minute 700 were $a, b = 7.828(1) \text{ \AA}$, $c = 11.912(3) \text{ \AA}$

continued diffusion takes place with the filling of the Cs1 site while the occupancy of the Cs2 site remains static.

The results of the time-resolved x-ray diffraction study of Cs^+ exchange into Na-TS illustrated a crystallographic-site-dependent process. Cesium first occupies site Cs2, located outside of the 8MR, dur-

Fig. 49.24 Occupancy refinement of the Cs^+ sites Cs1 and Cs2. Cs2 is not shown because the refinements were 0.00(1) occupancy. The two-step process of Cs occupancy corresponds with the unit cell trends (Fig. 49.22). Cs^+ fractional occupancy at minute 200 was 0.115(6) and at minute 700 was 0.339(7)

ing which time water occupancy at site OW2 decreased rapidly. The process of loading site Cs2 occurred within 250 min, and was much slower in comparison with Cs^+ exchange into H-TS. When OW2 occupancy had reached zero, Cs^+ exchanged into site Cs1 located at the center of the 8MR. The reduction in water occupancy in the center of the 8MR during Cs^+ exchange for Na^+ may be caused by spatial restrictions due to the incorporation of the large Cs^+ ionic radius at site Cs2, and indirectly forces water to migrate out of the channels. This suggests that direct replacement of Cs^+ for Na^+ was favored, and the disruption of the water-hydroxyl bond network in the center of the 8MR was not favored. Once the OW2 occupancy reached zero, the Cs1 site became available and dominated the exchange process.

Although structure refinements of Cs^+ exchange into Na-NbCST could not be preformed, a possible scenario of the exchange process may be inferred in conjunction with previous static exchange studies [49.34] and these time-resolved studies. Starting

with the unit cell parameters (Fig. 49.18) as a basis for the argument, the ion exchange may have proceeded in two distinct steps. The first step was Cs^+ uptake into site Cs1, where no H_2O occupied the center of the circular 8MR. This was indicated by a nonlinear increase in the *a*- and *b*-axes lengths and a decrease in the *c*-axis length. Incorporation of Cs^+ at site Cs1 would have continued for at least 235 min along the continuous unit cell lengths trajectories. Between minutes 235 and 287 no x-ray beam was available, but a decrease in the *a* and *b* cell lengths occurred, while the *c*-axis maintained a decreasing trajectory. The decrease in the *a* and *b* cell lengths would be the onset of the second step, and at this point, site Cs^+ would have started to fill site Cs2. The availability of site Cs2 would have been initiated by a decrease in OW2 occupancy. Similar exchange mechanisms were observed in the case of Cs^+ into Na-TS, where the Cs2 site filled first to force OW2 out of the structure, and once OW2 achieved a fractional occupancy of ≈ 0.1 , Cs^+ began to fill site Cs1.

49.8 Summary

An understanding of the time-dependent nature of chemical reactions and processes is essential for the quantitative description of synthesis processes and ion-exchange mechanisms. Current time-resolved diffraction techniques do not have enough resolution to be used as the sole method for modeling complex crystallographic relationships. With current technologies and techniques, in situ diffraction studies must also be complemented by ex situ diffraction studies of the end-member phases. The kinetics of material synthesis observed here can be described as a series of compound precursor phases that eventually lead to the desired product as a result of changing gel compositions from precipitating phases. Only using in situ techniques can these cursory phases be described in the four-dimensional space of time, temperature, pressure, and composition. In addition, the intermediate precursor phases may themselves be important materials that

would normally go unnoticed during ex situ synthesis. In any case, the crystallographic and chemical make-up of the cursory phases will elucidate the mechanisms of crystal growth.

In situ ion-exchange studies illustrate the complex mobility of ion and water mobility within the voids of crystalline phase, and the time and structure dependency of the ion-exchange pathway. These types of in situ time-resolved diffraction studies can be extremely useful in understanding the selectivity and fundamental mechanisms of the ion-exchange process in open-framework materials.

While we have concentrated on the latest results from our own in situ studies, it should be recognized that many other techniques are used as in situ time-resolved procedures, particularly for crystal growth studies. A representative few are listed [49.43–48] to illustrate the extent and power of in situ methods.

50. Single-Crystal Scintillation Materials

Martin Nikl, Anna Vedda, Valentin V. Laguta

Scintillation materials are employed to detect x-ray and γ -ray photons or accelerated particles. Wide-bandgap semiconductor or insulator materials with a high degree of structural perfection are suitable for this purpose. They must accomplish fast and efficient transformation of incoming high-energy photon/particles to a number of electron-hole pairs collected in the conduction and valence bands, respectively, and their radiative recombination at suitable luminescence centers in the material. Generated ultraviolet (UV) or visible light can then be detected at high sensitivity by conventional solid-state semiconductor- or photomultiplier-based photodetectors, which are an indispensable part of scintillation detectors.

An insight into this field will be provided for a wider scientific audience and at the same time we will point out some current hot topics. After reviewing the historical issues and fundamental physical processes of the x(γ)-to-visible light transformation occurring in scintillators, practically important material parameters, characteristics, and related measurement principles will be summarized. An overview of selected modern single-crystal and optical ceramic materials will be given. Particular attention will be paid to the relation between the manufacturing technology used and the occurrence of material defects and imperfections. The study and understanding of related trapping states in the forbidden gap and their role in the energy transfer and storage processes in the

material will be shown to be of paramount importance for material optimization. Correlated experiments of time-resolved luminescence spectroscopy, wavelength-resolved thermally stimulated luminescence, and electron paramagnetic resonance offer a powerful tool for this purpose. Future prospects and directions for activity in the field will be briefly mentioned as well.

50.1 Background

In the introductory part of this chapter, the history of scintillator material development will be briefly reviewed. Fundamental aspects of x(γ)-ray transformation to ultraviolet/visible photons will be explained and

practical scintillation parameters will be listed, which will aid in the quantitative evaluation of candidate materials. Preparation techniques, occurrence of defects, and their role will be discussed. Finally, experimen-

tal techniques suitable for correlated characterization of physical phenomena in scintillators will be described.

50.1.1 Historical Aspects

In November 1895 Wilhelm Conrad Röntgen noticed the glow of a barium platinocyanide screen placed next to his operating discharge tube, thus discovering a new invisible and penetrating radiation [50.1, 2], named *x-rays* in English or *Röntgen radiation* in some other languages. For *x-ray* registration, simple photographic film was found to be rather inefficient and the search for materials able to convert *x-to-visible* started immediately in order to couple with sensitive photographic-film-based detectors. Pupin introduced CaWO_4 powder, which was used for this purpose for more than 75 years. Together with ZnS -based powders introduced later by Crookes and Regener, CaWO_4 powder is the oldest phosphor material employed for detection of *x-rays*.

In early 1896, the natural radioactivity (spontaneously released high-energy radiation) of uranium was discovered by *Henri Becquerel* [50.3] and followed by pioneering works of *Marie Curie Skłodowska* and her husband *Pierre Curie*, which led to the discovery of the strongly radioactive elements polonium and radium [50.4, 5]. This kind of radiation is commonly named *gamma rays* and its energy is higher than the above-mentioned *x-rays*. Among the various methods for the detection of *gamma radiation*, scintillator-based detectors have been widely employed. It is also interesting to note that, in 1897, the cathode ray tube was invented by Braun, in which the energy of an accel-

erated electron beam is converted into visible light (in a process called *cathodoluminescence*) by a phosphor material. The mechanism of this conversion is quite similar [50.6] to that functioning in the case of *x-ray* conversion. Thus, at the end of the 19th century, two energetic (photon and particle) radiations were available, together with *gamma rays* generated by natural radioactive elements. Their enormous application potential was realized especially during World War I, which stimulated the development of phosphor and scintillator materials necessary for their practical exploitation.

The history of single-crystal scintillators begins in the late 1940s with the introduction of NaI:Tl and CsI:Tl scintillators by *Hofstadter* [50.7, 8]. Since that time a number of material systems have been reported, see Fig. 50.1 and [50.9] for an overview. The above two materials and $\text{Bi}_4\text{Ge}_3\text{O}_{12}$ (BGO), introduced by *Weber* and *Monchamp* [50.10], became widespread scintillator materials and are often used as *standard samples* to evaluate newly developed materials. Within the last 15 years there has been considerable activity in this field, triggered mainly by the needs of high-energy physics and advanced imaging applications in science, medicine, and industry. This has led to a considerable number of articles in the literature dealing mostly with Ce^{3+} -doped materials, due to the fast decay time of the $5d-4f$ radiative transition of the Ce^{3+} center (typically 20–60 ns) and its high quantum efficiency (close to 1) at room temperature (RT). For reviews see [50.11, 12].

Due to the great practical importance and relatively long history of this field, there already exists a large amount of published information on the topic. Let us mention the superb recent survey of luminescent materials by *Blasse* and *Grabmaier* [50.13], the overview of methodology in use in the radiation measurement by *Knoll* [50.14], the monograph devoted to scintillator materials from *Rodnyi* [50.15], and the useful phosphor handbook written by *Shionoya* and *Yen* [50.16]. Numerous featured review papers on phosphor and scintillator materials and their applications exist in the scientific literature as well, for instance [50.17–22].

50.1.2 Fundamentals

Wide-bandgap materials are employed for transformation of the $x(\gamma)$ -ray to ultraviolet/visible photons; see the sketch in Fig. 50.1. Consistent phenomenological descriptions of the scintillation conversion process, efficiency criteria, etc., were developed already in the 1970s [50.23] and later further refined [50.24]. Scintillation conversion is a relatively complicated pro-

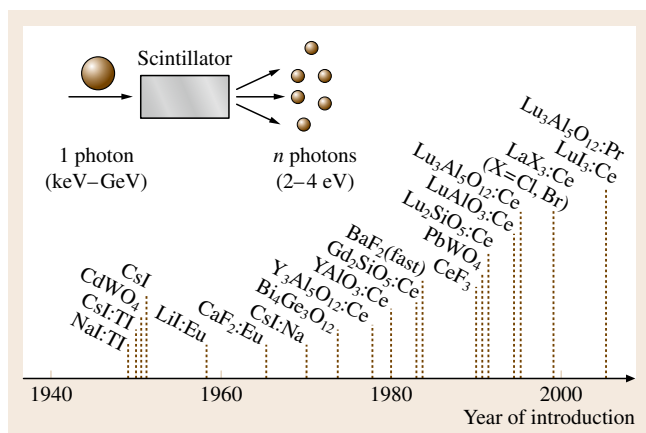

Fig. 50.1 Sketch of the scintillator principle and a timeline of single-crystal scintillators

Fig. 50.2 Sketch of scintillator conversion of a high-energy (HE) photon

cess, which can be divided into three consecutive subprocesses: *conversion*, *transport*, and *luminescence* (Fig. 50.2). During the initial conversion a multistep interaction of a high-energy photon with the lattice of the scintillator material occurs through the photoelectric effect, Compton scattering effect, and pair production; for photon energies below 100 keV the first of these is of major importance. Many electron-hole pairs are created and thermalized in the conduction and valence bands, respectively. This first stage is concluded within less than 1 ps. More detailed considerations about the conversion processes have been published in [50.25, 26]. In the transport process electrons and holes (eventually created excitons) migrate through the material, repeated trapping at defects may occur, energy losses are probable due to nonradiative recombinations, etc. Considerable delay in the migration can be introduced due to this charge-carrier recapture at trapping levels in the material forbidden gap. This stage is the least predictable, as point defects, flaws, surfaces, and interfaces can introduce energy levels into the forbidden gap and strongly modify/degrade otherwise high intrinsic scintillation performance. These phenomena are strongly dependent upon manufacturing technology [50.27]. During the final stage, luminescence consists of consecutive trapping of the electron and hole at the luminescent center and their radiative recombination. Nonradiative energy transfer towards the emission center via exciton-based state is also possible. In a particular group of mater-

ials the light generation occurs in radiative transitions between the valence and first core bands (sketched in Fig. 50.2); these are so-called cross-luminescence scintillators [50.15]. The latter mechanism enables very fast, even subnanosecond, scintillation response, which is, however, usually accompanied by much slower exciton-related luminescence. This phenomenon is reported in the literature mainly for BaF₂ and other halide single crystals [50.28]. The physics of luminescent centers is usually well understood due to advanced experimental methods available for their selective and time-resolved study; see, e.g., [50.13, 14].

50.1.3 Material Characteristics

As mentioned above, in the early days of x-ray usage, just phosphor powders in the form of thin screens were employed for their registration, coupled together with a photographic film [50.17]. Later, due to the need to additionally detect and monitor higher-energy x- or γ -rays, scintillator materials were introduced in the form of single crystals (Fig. 50.1).

Despite the fact that the underlying physics is identical, scientific communities working on phosphors and scintillators have been partially separated, mainly due to the different demands of related applications and different preparation technologies employed [50.16–18]. Commonly, materials are called phosphors when used in applications using photon-integrating (steady-state) mode detection, while scintillators are employed in the (x- or γ -ray) photon-counting regime. Today, the separation between phosphor (powders) and scintillator (solid state) materials is somewhat diminished as some materials are used in both detection modes, in powder, bulk or other forms, depending on the application [50.21].

Scintillation Parameters

In the case of scintillators, x(γ)-ray photon counting consists of accumulating the generated light arriving soon after the initial conversion stage is accomplished (Fig. 50.2), as the scintillator works as a high-energy photon counter. Strongly delayed light, e.g., due to retrapping processes mentioned above cannot be technically exploited in the counting mode. Also x(γ)-ray photons of different energy should be resolved for some applications. The most important characteristics of scintillation materials for detectors are as follows:

1. Light yield (LY)
2. X(γ)-ray stopping power

3. Scintillation response – decay time
4. Spectral matching between the scintillator emission spectrum and photodetector
5. Chemical stability and radiation resistance
6. Linearity of light response with the incident $x(\gamma)$ -ray photon energy – energy resolution.

The overall scintillation efficiency of $x(\gamma)$ -ray-to-light conversion is determined by both intrinsic and extrinsic material characteristics. The number of UV/visible photons N_{ph} produced in the scintillation conversion per energy E of incoming $x(\gamma)$ -ray photon can be expressed as [50.23–25]

$$N_{\text{ph}} = [E/(\beta E_g)]SQ, \quad (50.1)$$

where E_g represents the forbidden gap of the material, S and Q are the quantum efficiencies of the transport and luminescence stages, respectively, and β is a phenomenological parameter which is typically found to be 2–3 for most materials. The relative efficiency can then be obtained as

$$\eta = E_{\text{vis}}N_{\text{ph}}/E, \quad (50.2)$$

where E_{vis} is the energy of generated UV/vis photons. The most efficient material among the phosphors and scintillators today is ZnS:Ag with $\eta \approx 0.2$. If we consider that the bandgap of the scintillator materials discussed herein is higher than that of ZnS (≈ 3 eV), then even more efficient materials could be found within those with yet narrower bandgap.

The LY of a scintillator is always an inferior value in terms of (50.1) as it represents the fraction of generated visible photons that arrived at the photodetector within a certain time gate after the high-energy photon absorption; typical values of such a time gate are in practice set between 100 ns and 10 μ s.

The $x(\gamma)$ -ray stopping power (attenuation coefficient) for a material of given thickness depends on its density ρ and its effective atomic number Z_{eff} (for the calculation of Z_{eff} ; see, e.g., [50.18]). Considering only interaction through the photoelectric effect, the stopping power is proportional to $\rho Z_{\text{eff}}^{3-4}$ [50.20].

The kinetics of the light response of a scintillator are governed by the characteristics of the transport and luminescence stages in Fig. 50.2, as they are far slower than the initial conversion. The decay rate of the luminescence center itself is defined by its transition dipole moment from the excited to ground state and can be further enhanced by additional nonradiative quenching or energy transfer processes away from the excited state. Such quenching or energy transfer, however, results in

the decrease of parameter Q in (50.1), and the overall conversion efficiency is also decreased. In the most simple case of exponential decay, the emission intensity $I(t)$ is

$$I(t) \approx \exp(-t/\tau), \quad (50.3)$$

where τ is the decay time. While decay times of the parity and/or spin-forbidden transitions for most rare-earth ions are typically of the order of several tens of μ s up to ms, in the case of allowed 5d–4f transitions of Ce^{3+} and Pr^{3+} the values scale down to tens of nanoseconds, and fully allowed singlet–singlet transition in organic molecules is still about ten times faster [50.29]. The fastest emission transitions are offered by the radiative decay of Wannier excitons in direct-gap semiconductors, where subnanosecond values have been reported for compounds such as ZnO, CuX, CsPbX_3 ($X = \text{Cl}, \text{Br}$), PbI_2 , and HgI_2 [50.30]. The emission rate is enabled by the coherent nature of the exciton state spread over a (large) number of elementary cells [50.31]. However, a serious disadvantage of the latter group of materials is the lower binding energy of their excitonic state, which results in partial ionization and consequently quenching of the exciton-related emission at RT. In bulk materials, further efficiency decrease follows from the small Stokes shift, which leads to noticeable reabsorption losses [50.32].

Due to the aforementioned re trapping processes during the transport stage sketched in Fig. 50.2, the light emission response of a material under high-energy excitation is often further complicated by slower non-exponential components. These processes are currently quantified by the afterglow (sometimes called a persistence), which is defined like a residual light intensity at some time (from a few ms to min) after the excitation is cut off [50.27]. The delayed radiative recombination will contribute to slow scintillator response, lower LY values, and worse signal-to-background ratio [50.33]. In some studies, a parameter α has been introduced to provide a comparative measure for the occurrence of delayed radiative recombination within tens to hundreds of μ s. Due to the repetitive nature of the measurement, they are reflected in the signal level before the rising edge of the decay curve [50.33, 34], as illustrated in Fig. 50.3. In practical evaluation of both phosphors and scintillators, sometimes simple 1/e or 1/10 decay times are provided, which are defined as the time when the light intensity decreases to 1/e or 1/10 of its initial intensity after a flash excitation, or the so-called mean decay time can be calculated [50.22].

Fig. 50.3 Spectrally unresolved scintillation decay of undoped PbWO_4 , fitted by three exponential functions, $I(t)$, convoluted with the instrumental response (solid line). The true background level is displayed as well. Background enhancement in the repetitive decay measurement is reflected in I_{ss} , the superslow decay component amplitude which comes from preceding excitations and is evaluated using the coefficient α

Spectral matching between the scintillator emission band and the photodetector spectral sensitivity dependence is an obvious requirement. Classical criteria were defined some time ago as near-UV/blue emission is optimum for a photomultiplier detector, while for a photodiode the green–red spectral region was considered best. In recent years enormous development of semiconductor photodetectors has occurred and the latest generation of back-illuminated charge-coupled devices (CCDs) show enhanced sensitivity down to 200 nm.

Chemical stability concerns mainly the hygroscopicity of materials, which in some cases severely limits their long-time operation in the open air (NaI:Tl , CsI:Na , and $\text{LaX}_3\text{:Ce}$ with $\text{X} = \text{Cl, Br}$).

Radiation resistance of materials regards mainly the performance changes and instabilities due to the induced absorption resulting from material irradiation and creation of color centers. It is a matter of concern mainly in bulk scintillation materials [50.22]. In the case of overlap between induced absorption and the emission spectrum, reabsorption losses occur with resulting loss of overall efficiency and LY. An example of this behavior is shown in Fig. 50.4. While this parameter has been considered mainly in research into scintillators for high-energy physics, it should be noted that it has importance also in several medical imaging techniques [50.20] and in the case of industrial flaw de-

Fig. 50.4 Absorption spectra of 2 cm-thick $\text{YAlO}_3\text{:Ce}^{3+}$ single crystal before and after γ -ray irradiation (^{60}Co , 500 Gy dose) at RT. Overlap of the irradiation-induced absorption with luminescence spectrum of the material is demonstrated

tection or synchrotron beam diagnostics applications as well.

The linearity of light response with incident $x(\gamma)$ -ray photon energy in scintillators can be monitored through the dependence of LY on the incident photon energy. The value for LY is energy dependent, partly due to abrupt changes of the attenuation coefficient around the K and L edges of the elements constituting the compound, but also due to the nonequal conversion efficiency of the photoelectric and Compton scattering effects, which become progressively more important with increasing energy of incoming $x(\gamma)$ -rays. As a result the energy resolution of a scintillator material is degraded with respect to the intrinsic limits based purely on statistical grounds [50.35].

The methodology of radiation detection is described in [50.14]. To quantify the characteristics and parameters described above, the set of usually used routine methods is described in [50.21].

Preparation Technology and Material Defects

Single-crystal scintillators are readily manufactured using crystal growth from the melt, i. e., by Czochralski, Bridgman or similar techniques. Though such techniques are well established and large crystals can be grown [50.36], point or extended defects are present in these artificial materials and often limit their performance. In recent years, the micropulling down growth technique has become frequently reported in the literature [50.37]. Enabling synthesis of circular or shaped

Fig. 50.5a,b Single crystal with square rod shape grown by the micropulling-down method: **(a)** sapphire single crystals and **(b)** LuAG single crystal (after [50.38])

single-crystal fibers of diameter up to several millimeters (Fig. 50.5) grown from the melt and of very good structural quality, this is a fast and economic research tool in the search for new scintillator materials [50.38] or in producing *device-size* crystal elements without the need for extensive cutting and polishing procedures.

The transport stage of scintillator conversion (sketched in Fig. 50.2) was mentioned as a critical and unpredictable period, during which the material performance can be degraded due to defects and flaws arising in the manufacturing process. In all materials, intrinsic point defects arise (e.g., cation and anion vacancies, interstitial atoms) as a result of general thermodynamic conditions and are further accompanied by extrinsic point (accidental impurities) or extended (dislocations, grain and domain interfaces) defects. In many cases, such defects introduce energy levels in the forbidden gap, which can be involved in the capture of migrating charge carriers. In the process of material optimization it is necessary to diminish or deactivate such defects to increase the material performance to its intrinsic/theoretical limit. In the case of accidental impurities or extended structural defects, the solution consists of material purification and optimization of the technological process to improve material purity and structure. However, in case of intrinsic defects, alterna-

tive solutions are pursued such as codoping the material by aliovalent ion(s) that do not participate in the energy transfer and storage processes. Due to the different charge state of the dopant ion (with respect to the original substituted lattice ion) the Coulombic equilibrium of the lattice is changed and this usually induces changes in the concentration of intrinsic point defects. Examples are the optimization of PbWO_4 by doping or codoping with trivalent ions at the Pb^{2+} site [50.22], the codoping with Zr^{4+} in $\text{YAlO}_3\text{:Ce}$ [50.39] or the recent discovery of positive influence of Eu^{2+} codoping in CsI:Tl to reduce its afterglow [50.40].

50.1.4 Characterization Methods

To understand the relation between material defects and the occurrence of traps in the material forbidden gap, their involvement in energy capture and storage, and interconnection with the production technology, a set of specific characterization methods must be used in close coordination with the manufacturing technology. Correlated experiments using time-resolved luminescence spectroscopy, wavelength-resolved thermally stimulated luminescence, and electron spin resonance in an extended temperature interval (10–300 K at least) are very powerful tools for this purpose.

Time-resolved UV/visible emission spectroscopy enables detailed understanding of the luminescence center itself, its intracenter transitions, and eventual nonradiative quenching pathways [50.13, 41]. At the same time its interconnection with the host lattice environment via energy transfer processes can be monitored. Selective pulse excitation in the vacuum ultraviolet (VUV)/UV/visible spectral region completed with x-ray or single-photon gamma-ray excitations is used for this purpose.

Thermally stimulated luminescence (TSL) or thermoluminescence allows the study of point defects giving rise to localized energy levels (traps) in a material forbidden gap. A TSL measurement is a two-stage process, which involves at least one electron trap and one hole trap. A highly simplified scheme is proposed in Fig. 50.6; see [50.42, 43] for a systematic description of these phenomena and measurement schemes. During irradiation at a given temperature (RT or cryogenic) free carriers are trapped at electron or hole centers. A subsequent heating cycle allows the carriers in shallow traps to be released and to recombine radiatively with carriers of the opposite sign stably localized at recombination centers. In the example scheme illustrated, electron traps are emptied while hole traps act as re-

Fig. 50.6 Sketch of the TSL process

combination centers. The emitted light as a function of temperature (glow curve) displays a peak at a characteristic temperature related to the trap structure. If, before recombination, electrons are transferred to the conduction band, a thermally stimulated conductivity (TSC) signal can also be measured. In the simplest first-order kinetics model [50.42, 43] the intensity $I(t)$ of emitted photons is

$$I(T) = sn_0 \exp\left(-\frac{E_T}{k_B T}\right) \times \exp\left[-\frac{s}{\beta} \int_{T_0}^T \exp\left(-\frac{E_T}{k_B T'}\right) dT'\right], \quad (50.4)$$

where n_0 (cm^{-3}) is the number of traps filled by irradiation, s (s^{-1}) is a frequency factor, β is the heating rate, and E_T (eV) is the trap depth. In the same simplified model, if instead of being heated the sample is held at a constant temperature after irradiation, the mean time spent by carriers in the trap before recombination is

$$\tau = \frac{1}{s} \exp\left(\frac{E_T}{k_B T}\right). \quad (50.5)$$

This time governs the phosphorescence which can be spontaneously emitted at constant temperature. According to trap parameters, τ can vary in a very wide interval from ns– μs to hundreds or thousands of years. In suitable cases a detailed analysis of (50.4) or of more general ones by numerical methods [50.42, 43] results in the determination of the trap parameters (E_T , s). The mean time τ at RT can thus be evaluated, allowing direct comparison with slow components in time-resolved scintillation measurements or correlation with LY. Spatial correlation between traps and recombination centers can also sometimes be elucidated. Moreover, more detailed information can be obtained by measuring the wavelength spectrum of the emitted light (see the example in Fig. 50.6). So, whereas temperature resolution can separate different trapping processes, measurement of the TSL emission spectrum can evidence different recombination processes when several centers act simultaneously.

The nature and local structure of the defects, traps, and recombination centers mentioned above can be studied in a detailed manner by electron spin resonance (ESR) and related methods such as electron nuclear double resonance (ENDOR) and optically detected magnetic resonance (ODMR) [50.44, 45]. All of these methods are so-called local methods and exploit the interaction of the magnetic moment of the

Fig. 50.7 ESR measurement principle

unpaired electron(s) or hole(s) and of the nuclei in a defect with each other and with external magnetic fields.

In a magnetic resonance experiment, the position of the resonance lines reflects both local symmetry and degree of lattice distortion around paramagnetic particle. In addition, the electron–nuclear interaction can give direct evidence for the nuclear (thus also the chemical) species coupled to the paramagnetic particle. This can be illustrated in Fig. 50.7 with an example related to the Pb^+ center in a PbWO_4 crystal [50.46] where an electron is localized at the Pb^+ p_z orbital around an oxygen vacancy. With the application of an external magnetic field B_0 the lowest energy level of Pb^+ splits nearly linearly with field strength. The microwave energy is absorbed by the sample when the frequency of the irradiation is in resonance with the energy splitting. For lead ions with nonzero nuclear spin there is an additional splitting of the energy levels (hyperfine splitting) due to the interaction of electron and nuclear magnetic moments, which gives rise to low-intensity satellites around the main resonance. Detection of hyperfine satellites in many cases allows unambiguous determination of the local structure of defects.

In favorable cases one can thus gain the following information from ESR experiments:

1. Symmetry of a defect
2. Concentration of defects

- 3. Identification of nuclei (atoms) constituting a defect
- 4. Charge state of paramagnetic ion(s) involved
- 5. Change of defect charge state under external influences (irradiation, temperature, etc.)
- 6. Dynamic properties of a defect, e.g., decay or growth of the concentration of defects after the irradiation is switched on (off).

The last item allows the direct determination of the energy of the local electronic level of a defect created by irradiation and thus can be correlated with TSL characteristics.

Further refinement of the electronic structure of absorption or luminescence centers can be obtained using the technique of optically detected ESR via magnetic circular dichroism (MCD) [50.45]. This technique provides a direct correlation between ESR and MCD by the *tagged MCD* method, when one keeps the magnetic field constant on one of the resonance positions and changes the wavelength at which the optical absorption or luminescence is detected. Therefore, ODMR offers the most compelling interrelation between atomic-scale defects and the related optical absorption or luminescence bands.

50.2 Scintillation Materials

Due to the wide variety of applications, about 20 candidate scintillator systems have been systematically studied, their manufacturing industrialized, and most of them also successfully commercialized to be used in scintillation detectors (Fig. 50.1). Parameters of selected materials are given in Table 50.1. In this section, an overview of several material systems introduced and/or intensively researched and optimized within the last 10–15 years will be given. Specifically, manufacturing technology aspects will be mentioned and essential luminescence characteristics will be described together with the materials’ scintillation performance. Further emphasis will be placed on the description of point defects, which are typical for each material group, and to their role in the processes of energy transfer and

capture in a scintillator. Correlated use of several experimental techniques and well-defined samples is vital to gain necessary insight into the underlying complex physical phenomena at the atomistic level. The optimization of scintillation materials toward their intrinsic limits can then be guided by knowledge gained about the limitations in the scintillator conversion and their relation to the manufacturing technology.

50.2.1 Lead Tungstate (PbWO₄) Single Crystals

Single crystals of PbWO₄ (PWO) were the subject of increased interest for scintillation detection in the early 1990s because of their potential use in electromag-

Table 50.1 Survey of characteristics of selected single-crystal scintillators (for those based on rare-earth halides, see Table 50.2). Light yield values are spectrally corrected

Crystal	Density (g/cm ³)	Light yield (phot/MeV)	Dominant scint. decay time (ns)	Emission maximum (nm)	$\Delta E/E$ at 662 keV (%)

netic calorimeters – the inner parts of huge detectors used in high-energy physics accelerators. The essential luminescence characteristics of **PWO** had already been studied by the 1970s [50.47–49] and the growth of tungstate and molybdate single-crystal systems was also reported in the literature [50.50]. However, the first systematic scintillation-oriented reports appeared in 1992 [50.51, 52], showing the favorable characteristics of **PWO** for the above-mentioned applications.

PWO melts congruently at 1123 °C. It shows an exceptionally high density (8.28 g/cm³) when compared with other scintillators. It exists in several structural modifications, but only the scheelite structure characterized by the tetragonal space group *I41/a* or *C4h* can be obtained using the high-temperature melt-based methods. Both Czochralski [50.53] and Bridgman [50.54] methods have been widely employed, and industrial size crystals up to about 30 cm length and 7–10 cm diameter were grown [50.55, 56]. The stoichiometry of the melt [50.57, 58], atmosphere of the growth, and postgrowth annealing [50.59] were widely studied to optimize the scintillation performance. Once the growth process was optimized, the doping of PbWO₄ by selected trivalent ions was employed as another efficient tool to further increase the figure of merit of this scintillator. See [50.22, 55, 56] for reviews of reported results.

It is well established that the **PWO** emission spectrum consists of two dominant components. The blue component, peaking at ≈ 420 nm (2.9 eV), was ascribed to the regular lattice center, namely the (WO₄)^{2−} group [50.47, 48], and identified later as the self-trapped exciton (**STE**). At higher temperatures, however, this component originates from various localized exciton states, because the **STE** is thermally disintegrated around 150 K [50.60, 61]. The green component, peaking at 480–520 nm (≈ 2.5 eV), was ascribed to a defect center (WO₃) [50.49]. Moreover, a Mo impurity (i. e., the (MoO₄)^{2−} group) was also found to give rise to an emission component at 520 nm [50.62, 63]. Temperature dependencies and temporal characteristics of these two green emissions were studied in detail and compared in a number of different **PWO** crystals [50.64]. Photoluminescence of **PWO** is heavily quenched at **RT**; this is the reason why its scintillation response is dominated by a decay time of a few ns only and its **LY** is very low (Table 50.1).

The decay kinetics of the blue and green emission components has been reported already in [50.47, 48]. Very slow nonexponential components have been observed in the 10^{−6}–10^{−4} s time scale even under selective excitation within the lowest absorption peak

of **PWO** above 180 K [50.65, 66], or in the scintillation decays excited by the 511 keV photons of ²²Na radioisotope [50.34, 67]. The thermally induced decomposition of the **STE** and excited green emission centers above 150 and 200 K, respectively [50.61, 68], establishes an intrinsic equilibrium between the localized and free electron–hole states at higher temperatures. This explains the coexistence of the first- and second-order decay mechanisms due to the prompt and delayed radiative recombination processes, respectively, observed clearly in the decay at **RT** [50.66] (Fig. 50.8). Undesirable slowing of the luminescence response was observed especially in **PWO** samples containing the WO₃ green emission centers [50.64].

Because of the mentioned thermal disintegration of the excited emission centers, any shallow trap states in the **PWO** lattice taking part in carrier capture processes become important. They modify the migration characteristics of free charge carriers through retrapping. Consequently, the speed of their delayed radiation recombination is altered. Monitoring such trap states by **TSL** measurements was reported some time ago [50.69], and more recent measurements confirm the rather rich variety of such shallow trap states in the **PWO** lattice [50.66, 70, 71], which are strongly dependent upon synthesis route. Simultaneous use of **TSL** and **ESR** experiments was applied efficiently to gain understanding about the nature of traps and details about the energy storage in **PWO** lattice. Specifically, electron self-trapping at the (WO₄)^{2−} complex anion was revealed by **ESR** [50.72]. The related paramag-

Fig. 50.8 Photoluminescence decay kinetics at **RT** of Mo-doped (160 ppm) **PWO**. $\lambda_{\text{ex}} = 308$ nm (XeCl excimer laser)

Fig. 50.9 Temperature dependence of ESR (dashed line) and TSL (solid line) signals related to $(\text{WO}_4)^{3-}$, $\text{Pb}^+-\text{V}_\text{O}$, and $(\text{WO}_3)^--\text{A}^+$ electron centers. In the inset the TSL emission spectra within the given temperature intervals are shown

netic $(\text{WO}_4)^{3-}$ center can survive up to about 50 K and its thermal disintegration is accompanied by a TSL peak (Fig. 50.9) [50.73]. In undoped PbWO_4 , a fraction of released electrons is stored in deeper $\text{Pb}^+-\text{V}_\text{O}$ traps [50.46, 74, 75], i.e., at the Pb^+ p-orbital around an isolated oxygen vacancy V_O , creating an F^+ center. This center is stable up to about 190 K and during its thermal disintegration again a TSL peak appears (Fig. 50.9). Similar to the situation at ≈ 50 K, a fraction of the released electrons are stored at still deeper traps, namely the oxygen-deficient $(\text{WO}_3)^--\text{A}^+$ complex (A^+ is a monovalent impurity or possibly a cation vacancy at a Pb position). Thermal destruction of this center occurs around 320–330 K and is again accompanied by a TSL peak [50.76]. It is worth noting that TSL emission spectra of the peaks at ≈ 50 , 190, and 320 K show maxima at different energies (inset of Fig. 50.9), pointing to the existence of three different hole traps. However, no detailed information about them could be obtained since no related hole centers have been detected by ESR thus far.

A significant change in the concentration of TSL-monitored trapping states was observed in PWO samples doped with large and stable trivalent A^{3+} ions ($\text{A}^{3+} = \text{La}^{3+}$, Y^{3+} , Lu^{3+} , and Gd^{3+}) [50.77–79]. Similar effects were obtained by using any of these dopants. Traps and related TSL peaks above 150 K were practically eliminated. La doping completely removes electron traps associated with oxygen vacancies and

stabilizes the self-trapped electron in its vicinity up to about 90–100 K [50.80]. New insight into the effect of La doping was recently gained in the study of doubly doped $\text{PbWO}_4:\text{Mo},\text{La}$ [50.81]. The Mo^{6+} ion is an efficient electron trap and the resulting $(\text{MoO}_4)^{3-}$ center is stable up to about 240–250 K [50.82]. Codoping with La resulted in a considerable increase of $(\text{MoO}_4)^{3-}$ center concentration, which was detected even without prior irradiation of the samples. Moreover, electrical conductivity above RT appeared and is governed by the same activation energy as that obtained from thermally induced disintegration of the $(\text{MoO}_4)^{3-}$ center. From these measurements, it was concluded that La^{3+} at Pb^{2+} sites introduces free electrons in the PbWO_4 conduction band, i.e., La^{3+} behaves as a donor impurity in a semiconductor. At the same time, a noticeable decrease of TSL signal related to $(\text{MoO}_4)^{3-}$ thermal disintegration around 240–250 K was found in doubly doped $\text{PbWO}_4:\text{Mo},\text{Y}$ [50.83]. To explain the increase of electron centers observed by ESR and the decrease of related TSL signal in trivalent-ion-codoped $\text{PbWO}_4:\text{Mo}$, the suppression of related hole traps must be considered. Hence, the effect of trivalent-ion doping has been understood, consisting of simultaneous suppression of oxygen vacancies and some of the hole traps. Furthermore, free excess electrons generated in the conduction band can fill electron traps of any kind. Such effects lower the capacity of the PbWO_4 lattice to trap and store generated charge carriers after x- or γ -irradiation. Consistently, the faster scintillation and photoluminescence decays are obtained [50.77, 84] and also the transmission [50.77, 84] and especially radiation resistance [50.78, 85] characteristics are noticeably improved (Fig. 50.10). Theoretical calculations established the energy levels of the defects based especially on vacancies and clarified further the effect of the La doping [50.86]. They are consistent with the experimental findings with the exception of the $\text{Pb}^+-\text{V}_\text{O}$ center, which was not found in the calculations.

For heavily A^{3+} -doped samples (above a few hundred molar ppm in the crystal), a decrease of LY was observed; this was explained by the possible creation of new nonradiative recombination traps related to La dimers/small aggregates [50.77]. Surprisingly, a very large concentration of trivalent ions could be accommodated in the PWO structure (even more than 10% of La) without significant loss of transmittance or radiation hardness. Due to extremely low LY, such heavily A^{3+} -doped PWO-based scintillators were proposed as a Cherenkov radiator [50.87]. Coulombic compensation of the excess charge of trivalent ions in such samples

was proposed as a self-compensation process in which a part of the La ions can reside at the W site [50.88]. Introduction of an interstitial oxygen was considered by the same authors as well [50.89]. Recent theoretical calculations favor the latter possibility [50.90].

Radiation damage processes and the nature of related defects were of special interest, because the resulting loss of transmission, instability of LY or even induced changes in the scintillation mechanism can strictly limit the applicability of PWO as a scintillator material in the severe radiation environments of planned detectors. Related deep traps must be stable enough at RT so that they are reflected in TSL glow curves above RT [50.91]. An attempt was made to decompose the induced absorption spectrum (inset of Fig. 50.10, curve *a*) into a sum of Gaussians, which should belong to particular color centers [50.91]. Based on correlated decomposition of irradiation-induced, high-temperature-annealing-induced, and as-grown undoped PWO absorption spectra, four bands were identified, peaking at 3.5, 2.9, 2.4, and 1.8 eV. Two components were found to contribute to the 3.5 eV band [50.92]. Ascription of these and other bands, extracted from absorption spectra, was attempted by several research groups [50.90–95]. However, none of these suggestions was supported by more conclusive methods such as ESR. An interesting suggestion about the physical origin of coloration of PbWO₄ was recently formulated [50.96], taking into account the variation of

tungsten valence in oxygen-deficient clusters, which can be created or destroyed by an appropriate post-growth annealing. In general, deep traps associated with radiation-damage-induced defects are expected to be rather complex, taking into account that the (WO₃)[−]-A⁺ electron trap responsible for the 300–330 K TSL peaks includes an oxygen vacancy and another defect nearby [50.76].

Recently, an effort has been made to increase the LY of PbWO₄ [50.97], which could allow its application outside of high-energy physics. Such a possibility is worth attempting since the thermal quenching of PbWO₄ emission is not due to intracenter quenching, but rather due to a nonradiative electron–hole recombination over the material bandgap [50.68] or around other defects [50.60]. If such thermally released electrons and holes can be efficiently and quickly radiatively recombined at an additional center, integral scintillation efficiency would rise. Doubly doped crystals (Mo, A³⁺) were reported, in which the LY value was increased about 3–4 times with respect to undoped material, while scintillation response was kept reasonably fast [50.98–100]. The effect of PbWO₄ nonstoichiometry on the LY value was studied as well [50.101]. Recently, another strategy was introduced, namely fluorine doping [50.102]. A common problem in all of these studies is that additional emission centers frequently give rise to additional shallow traps, which delay radiative recombination and keep the LY below ≈ 10% of BGO even if the integral scintillation efficiency could be increased up to a level comparable to BGO, i.e., about 25 times that of undoped PbWO₄ [50.103].

Fig. 50.10 Initial transmission and irradiation (⁶⁰Co radioisotope, 10 Gy dose) induced absorption of equivalently grown undoped (*a*) and La-doped (*b*) PbWO₄ single crystals (after [50.78])

50.2.2 Aluminum Perovskite XAlO₃:Ce (X = Y, Lu, Y/Lu)-Based Scintillators

Ce doping has provided scintillators with the highest figure of merit in this group of materials so far. Fast and efficient luminescence and scintillation is achieved due to the parity- and spin-allowed 5d–4f transition of Ce³⁺, which gives rise to the emission band at 360–370 nm (Fig. 50.11). Moreover, it is free from thermally induced nonradiative quenching at least up to 500 K. Luminescence of YAlO₃:Ce (YAP:Ce) was reported by Weber [50.104] and favorable properties of this material for scintillation applications were described later by Takeda et al. [50.105] and Atrata et al. [50.106]. A review paper devoted also to this group of scintillation materials has been published recently [50.22, 107].

Yttrium aluminate YAlO₃ has an orthorhombically distorted perovskite structure with space group *Pbnm*.

Fig. 50.11 Normalized radioluminescence spectra of doped YAlO_3 (see the legend) at RT

Crystals are grown from nonstoichiometric melt at temperatures of 1835–1875 °C [50.108], in which the 1 : 1 melt composition ($\text{Y}_2\text{O}_3:\text{Al}_2\text{O}_3$) is stable. In the case of LuAP this temperature region is shifted up by about 80 K. The nearly congruent growth of aluminum perovskites from high-temperature melt is further troubled by twin formation [50.109, 110]. Presence of light scattering centers was also reported [50.111]. The growth process is usually performed in Ar, Ar + H_2 or N_2 atmospheres or even under vacuum [50.108–112]. Optimized $\text{YAP}:\text{Ce}$ single crystals with Ce concentration up to 0.6 at.% in the crystal can be grown in boules up to about \varnothing 5 cm \times 15 cm in length in CRYTUR Ltd., Turnov, Czech Republic (Fig. 50.12). The boules of

Fig. 50.12 Zr-codoped $\text{YAP}:\text{Ce}$ single crystal (45 mm diameter and 125 mm length)

$\text{LuAP}:\text{Ce}$ grown by the Bridgman method [50.113] approach dimensions of about \varnothing 1.2 cm \times 6 cm in length with similar Ce concentrations. Due to the difficulties associated with the growth of pure LuAP single crystals (instability of perovskite phase and frequent appearance of the garnet one), attempts were made to grow mixed $\text{Y}_{1-x}\text{Lu}_x\text{AP}:\text{Ce}$ crystals ($x \leq 0.3$) [50.114]. Mixed $\text{Y}_{1-x}\text{Lu}_x\text{AP}:\text{Ce}$ ($0.15 \leq x \leq 0.8$) crystals were grown also by vertical Bridgman method [50.115]. Mixed (Y/Lu) $\text{AP}:\text{Ce}$ crystal growths, $x = 0.6$ –0.7, using Czochralski method, have been already mastered by a few industrial producers [50.116].

Five bands in the 180–300 nm region were clearly distinguished in the excitation spectrum [50.117] of the 370 nm emission of Ce^{3+} , in good agreement with the expected splitting of the 5d Ce^{3+} excited-state level due to the low Y^{3+} site symmetry. The 370 nm emission band shows a single-exponential fast photoluminescence decay (about 17 ns decay time) and slightly slower scintillation decay governed by decay time between 22 and 38 ns followed by a minor slow component of a few hundred ns [50.118, 119]. The latter component can be explained by delayed recombination of charge carriers at Ce^{3+} centers (similar to the recombination decay components in PbWO_4). The scintillation response of pure $\text{LuAP}:\text{Ce}$ is dominated ($\approx 80\%$ of the overall intensity) by the fast decay component of about 17–19 ns, and the rest of the intensity is released with a decay time of 160–180 ns. In the case of Lu-rich mixed ($x = 0.65$ –0.7) crystals, the intensity of the fast component is lowered considerably (40–54%) and accordingly the second slower component of about 190 ns decay time is more intense [50.116]. The origin of this degrading phenomenon has not yet been understood. High LY of $\text{YAP}:\text{Ce}$, up to 20 000–22 000 phot/MeV, was reported by several laboratories [50.120] (Table 50.1), decreasing with the admixture of Lu down to ≈ 12 000 phot/MeV in $\text{LuAP}:\text{Ce}$. In the process of energy transfer towards the Ce emission centers the excitonic mechanism was evidenced [50.117], but sequential capture of holes and electrons at Ce centers seems to be more important due to low efficiency of lattice exciton creation by hot electrons in the process of initial energy conversion in the YAP and LuAP lattices [50.121].

Doping aluminum perovskites by Pr^{3+} and Yb^{3+} was accomplished as well to obtain scintillators with still faster response with respect to the Ce^{3+} -doped ones; related radioluminescence spectra are shown in Fig. 50.11. The 5d–4f transition of Pr^{3+} provides a ≈ 1.5 eV high energy shifted and faster emission

with respect to the Ce^{3+} center in the host matrices with medium–strong crystal field, where the lowest 5d state is shifted below the $^1\text{S}_0$ level of Pr^{3+} . Both YAP:Pr [50.122] and LuAP:Pr [50.123] showed at least two times shorter dominant decay time with respect to the Ce-doped hosts. However, the reported LY is 2–4 times lower, so that their figure of merit is significantly degraded. The reason for the latter phenomenon is not clear as the RT quantum efficiency of Pr^{3+} luminescence center in YAP was found to be close to unity [50.124]. Cross-relaxation among Pr^{3+} ions [50.123] and lower efficiency of the energy transfer from the host to Pr^{3+} [50.124] were tentatively proposed as explanations.

Yb^{3+} doping gives rise to the charge transfer luminescence extending over near-UV and visible regions in a YAP host (Fig. 50.11). This luminescence mechanism became of renewed interest, as in the case of Yb^{3+} this kind of radiative transition is parity and spin allowed [50.125, 126] and the luminescence lifetime is typically below 100 ns. However, in most hosts it shows onset of thermal quenching well below RT, so that relatively low radioluminescence intensity and extremely fast, subnanosecond scintillation decay have been reported in $\text{Y}_{1-x}\text{Yb}_x\text{AlO}_3$ [50.127]. The highest radioluminescence intensity is obtained for $x = 0.3\text{--}0.4$. Favorably high Yb concentration is allowed due to limited concentration quenching in this system [50.128].

If one compares the results from different laboratories, the Ce^{3+} emission data in the YAP and LuYAP matrices exhibit slightly different shapes and position shifts. Several inequivalent Ce^{3+} positions were found also in ESR measurements [50.129]. The presence of stable Ce^{4+} ions is indicated in [50.130], and Ce^{4+} -related absorption transitions are ascribed to the parasitic absorption overlaying the region of the Ce^{3+} emission. Detailed studies of the temperature dependence of the LY below RT indicated the importance of shallow traps in the process of energy transfer in the YAP matrix; correlations between LY, TSL intensity, and scintillation decay were found and explained by a model based on the participation of trapping state(s) in the processes of electron transfer to trapped holes at Ce^{3+} sites [50.131]. However, no interpretation of the nature of the defects involved was proposed. Deeper electron traps related to TSL peaks at about 50 °C, 100–130 °C, 175 °C, and 225 °C in YAP:Ce and (Lu/Y)AP:Ce were ascribed to oxygen-vacancy-related defects; a thermally assisted tunneling process with the nearby lying Ce^{4+} hole center could

explain the calculated trap depth and frequency factors of these traps [50.132]. It is worth noting that in an early study [50.133] antisite defects (Y at Al site and vice versa) were considered for the stabilization of F or O^- centers, and their relation to various absorption bands in the 290–760 nm region was hypothetically assumed. The occurrence of color centers is a frequent problem in YAP and there are numerous studies in the literature dealing with this problem, [50.134, and references therein]. The induced absorption after γ -irradiation (radiation damage) of YAP:Ce was also reported [50.135] (Fig. 50.4), and bands peaking at 2.2–2.9 eV, ≈ 3.3 eV, and ≈ 3.89 eV were obtained by decomposition of the induced absorption spectra into Gaussian components. Deviation from stoichiometry, presence of transition-metal and rare-earth impurity ions, and temperature conditions during growth process strongly influence the presence and concentration of defects and color centers in as-grown crystals. Postgrowth annealing is frequently employed to decrease parasitic absorptions of the crystals in UV/visible spectral regions.

Literature information on intrinsic paramagnetic active defects in YAP crystals is rather limited. The autolocalization of holes in the form of O^- -bound small polarons was evidenced in YAP some time ago using ESR and optical techniques [50.136]. Recent ESR measurements of lightly (50 ppm) Ce-doped YAP have shown at least four different O^- center configurations caused by site inequivalence of the oxygen ions in the lattice. They are progressively transforming within themselves with increasing temperature as shown in Fig. 50.13. At the same time thermally induced decay

Fig. 50.13 Correlation between EPR intensity of O^- centers and corresponding TSL peaks in YAP crystals

Fig. 50.14 TSL spectra in the temperature range indicated in the legend and related to glow curves in Fig. 50.6. Curves for temperatures above 140 K refer to 50 ppm Ce. Curves are vertically shifted for clarity

of each O^- center is accompanied by a TSL peak. This means that, when a hole is liberated from an O^- center, it is either captured at a deeper hole trap or migrates until a localized electron is met and such electron–hole pair radiatively recombines giving rise to a TSL glow curve peak.

The site of the just mentioned radiative-recombination process was revealed from TSL emission spectra within the glow curve peaks (Fig. 50.14). Dominant glow curve peaks related to O_I – O_{III} annihilation show the emission at 3.5–4.0 eV ascribed to a localized exciton luminescence. Localization of excitons was assumed to be close to F or F^+ centers [50.137]. In undoped YAP, also time-resolved luminescence of F^+ and F centers themselves was reported at 350 nm and 440 nm, respectively [50.138].

The above hypothesis is further confirmed by finding F_A^+ centers in the same sample by ESR measurements [50.139]. They are also found in several configurations with gradually increasing stability within the range 200–300 K, which enables the radiative recombination suggested from TSL. The F_A^+ centers are attributed to the charged oxygen vacancy near the antisite yttrium ion where, however, electron density is essentially shifted to this antisite ion. Such a defect can be described to the Al^{3+} – V_O – $Y^{2+}(Al)$ complex. In a heavily Ce-doped sample, only the self-trapped hole O_I center survives and holes are dominantly trapped at Ce^{3+} ions, as evidenced in TSL spectra (Fig. 50.14). The TSL glow curve is dominated by another electron-

trap-related peak at 100–105 K, the origin of which is still unknown. Based on the recent finding in YAG:Ce that the TSL peak at 92 K is related to an electron trap around the Y_{Al} antisite defect [50.140] and taking into account the structural and chemical similarity of such a defect in both aluminum perovskite and garnet structure ($(Y_{Al}O_6)^{9-}$ octahedron) one can tentatively suggest a similar interpretation for the 100–105 K peak in YAP:Ce.

Impurity-related centers can come either from the raw materials or due to the particular synthesis technology used. In the former case, mainly iron [50.108] and titanium ions in YAP and furthermore Yb ions in (Lu/Y)AP were evidenced by ESR. In the latter case molybdenum ions were evidenced coming from the crucible used for the growth of bulk crystals [50.108, 112]. Mo^{3+} centers in YAP were described in detail with the help of ESR [50.141]. Being transition-metal elements with easily variable charge state they can be ionized and/or serve as nonradiative recombination centers.

The above-described color centers and impurity ions in YAP crystals give rise to local electronic levels in the forbidden gap, as presented in Fig. 50.15. The Ce^{3+} impurity ion is exploited as a fast and efficient radiative recombination center in YAP:Ce scintillator. In parallel, Mo and Ti impurities serve as ionization centers which produce free electrons and holes under irradiation with energy lower than the bandgap. The position of the Ti^{3+} level is about 4.2 eV above the valence band (VB) edge [50.142]. The Mo^{4+} level is somewhat lower as 330 nm UV irradiation is already enough to excite electrons from the VB to the Mo^{4+} ions, which become Mo^{3+} . The ionization energy of Ce^{3+} ions is at least 5.5 eV [50.143]. Migrating holes can be trapped or self-trapped by the O sublattice in the form of O^- -like

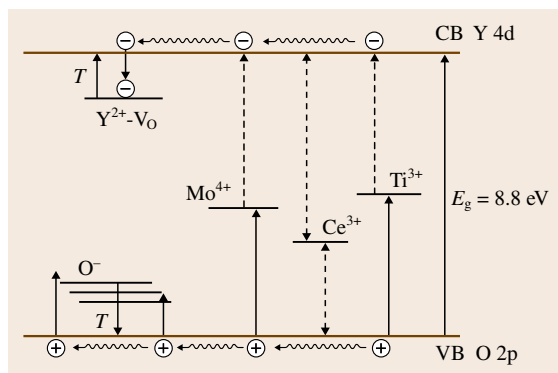

Fig. 50.15 scheme of local electronic levels of different defects in the forbidden gap of YAP

centers. The Y antisite ions give rise to the $Y_{Al}^{2+}-V_O$ defects acting as electron traps.

All the above-mentioned possibilities for hole and electron trapping can deteriorate scintillation performance of the crystal because they compete with or delay the radiative recombination at Ce^{3+} ions. In $YAP:Ce$, it has been proposed [50.131] that only 25% of the electrons generated by the ionizing photon/particle are transferred promptly to the Ce ion. The rest become trapped in three discrete sites. Consequently, there is considerable room for material optimization, particularly if the existence of these traps can be avoided. Such attempts have already been made by codoping with an aliovalent ion, which can change the Coulombic equilibrium and therefore the overall defect concentrations. Namely, Zr^{4+} codoping was used in $YAP:Ce$ [50.39, 144], which resulted in a dramatic decrease of deep oxygen-vacancy-related electron traps monitored by TSL above RT (Fig. 50.16). It is worth noting that recent atomistic calculations of Stanek et al. [50.145] dealt systematically with defect reaction energies in rare-earth aluminum perovskites and the above effect was explained considering the Frenkel recombination of Zr-induced oxygen interstitials with oxygen vacancies. Moreover, it has been shown [50.145, 146] that the relative importance of antisite and Schottky (vacancy) defects varies strongly with the cation size. While Schottky defects are of major importance in YAP , antisite defects might play a major role in $LuAP$. Such

a difference may be of some importance to explain the decreasing LY in $LuAP:Ce$. Combination of mentioned computer simulations and systematic experiments together with electronic structure calculations can provide a tool for deeper understanding of these scintillation materials and the possible technological approaches leading to their optimization.

50.2.3 Aluminum Garnet $X_3Al_5O_{12}:Ce$ ($X = Y, Lu, Y/Lu$)-Based Scintillators

Single crystals of $Y_3Al_5O_{12}$ (YAG) were among the first oxide materials grown by Czochralski technique during the 1960s [50.147]. Their development was stimulated mainly by the application for solid-state (Nd-doped) lasers, but soon the potential of Ce^{3+} -doped YAG single crystal for fast scintillators was realized as well [50.148]. The first comprehensive description of $YAG:Ce$ scintillator characteristics was reported by Moszynski et al. [50.149], who included this material among the high-figure-of-merit oxide scintillators. Isostructural $LuAG$ has a higher density (6.67 g/cm^3) than YAG (4.56 g/cm^3), which is advantageous in the case of hard x- and γ -ray detection (see the definition of stopping power in Sect. 50.1). $LuAG:Ce$ scintillator became of interest relatively recently [50.150, 151]. An early study of the Ce^{3+} and Pr^{3+} photoluminescence decay kinetics in YAG host [50.152] revealed the absence of nonradiative thermal quenching up to about 550 and 250 K, respectively. Consequently, at RT the 5d–4f transition of Ce^{3+} center can be exploited for fast and efficient scintillation in both YAG and $LuAG$ matrices.

The growth of YAG or $LuAG$ crystals by Czochralski technique provides large and high-quality crystals (Fig. 50.17), but also the micropulling down technique has been successful in growing single-crystal rods of comparable structural quality (Fig. 50.5). The former is usually accomplished using either an iridium crucible in an inert atmosphere (N_2) with small addition of oxygen [50.153], or a molybdenum crucible in a reducing ($Ar + H_2$) atmosphere [50.154]. Isostructural cubic garnet structures of YAG and $LuAG$ form a solid solution and any intermediate mixed composition can be grown. The solidification points of mixed compositions range between 2010°C ($LuAG$) and 1930°C (YAG) [50.153]. The garnet structure appears very flexible for cation substitution; such substitution was used to prepare materials with tailored lattice constants [50.155] and can, in principle, be used for the preparation of highly substituted crystals with homo-

Fig. 50.16 TSL glow curves of $YAP:Ce$ after irradiation at RT. Concentration of Zr in the sample is indicated on the curves, see also [50.39, 144]

geneous composition. However, at the same time this readiness of solid-solution formation in the garnet structure points to a relative ease of compositional defect formation. Ce^{3+} predominantly substitutes for the Y (Lu) cation, but a small fraction can be found at the anti-site (Al) position as well. The segregation coefficient of Ce^{3+} in YAG and especially in LuAG host is relatively small (less than 0.1), which is an obstacle to obtaining homogeneous doping profile in large crystals.

Due to high crystal field at the dodecahedral Y (Lu) site, the 5d states of Ce^{3+} are shifted to lower energy in garnet with respect to perovskite host. The lowest $4f-5d_1$ absorption and emission bands peak around 450–460 nm and in the green–yellow part of the spectra, respectively (Fig. 50.18). With the help of photoionization threshold and excited-state absorption measurements [50.156] it was established that the lowest $5d_1$ relaxed state is placed about 1.2 eV below the conduction band of YAG, which is enough to completely inhibit undesired ionization of Ce^{3+} relaxed excited state around RT. In a LuAG host, Ce^{3+} emission is high energy shifted by about 0.1 eV with respect to YAG, pointing to a somewhat weaker crystalline field and/or covalent bonding at the Lu site. Consistently, a slightly shorter Ce^{3+} photoluminescence decay time (≈ 55 ns) is obtained at RT in LuAG with respect to YAG (≈ 62 ns) host.

While the steady-state scintillator efficiency (radio-luminescence intensity) of both YAG:Ce and LuAG:Ce of high (5–6N) purity can reach up to 700–800% of that of BGO [50.33, 157], their LY is considerably lower. Namely, values up to 300 and 150% of

Fig. 50.17 LuAG:Ce crystal, $\varnothing 20 \times 30$ mm

Fig. 50.18 Absorption spectra of YAG and LuAG crystals at RT

BGO were reported for YAG:Ce and LuAG:Ce, respectively [50.120]. This points to a considerable amount of *slow scintillation light* in both materials. Very slow components are reflected in the *increased background* before the rising edge of the LuAG:Ce scintillation decay, which can be quantified by the already mentioned α coefficient (Fig. 50.3). It is worth noting that the *background* level is systematically higher in LuAG:Ce than in YAG:Ce of comparable doping level, quality, and purity [50.33] in agreement with the trend in their LY values. The scintillation decay of LuAG:Ce can be approximated by a two-exponential fit with decay times of about 55–60 ns and 300–1000 ns. A recent study of LuAG:Ce [50.158] has shown that the consecutive capture of a hole and an electron at Ce^{3+} centers is the dominant energy transfer pathway in the scintillation mechanism. More than 65% of the light in the LuAG:Ce scintillation decay is released in the above-mentioned slower decay component, which appears due to delayed radiative recombination at Ce^{3+} ions. The occurrence of slow decay components over an extended time scale suggests the existence of several traps with different thermal depths, which participate in charge-carrier trapping processes.

Scintillation decay characteristics of Pr^{3+} -doped YAG were reported for the first time in 1992 [50.122] and became of renewed interest recently [50.159] when, despite partially quenched emission of the Pr^{3+} center itself, spectrally uncorrected LY values of about 300% with respect to BGO and leading to a scintillation decay

component below 20 ns were measured in high-quality single crystals. Similar to Ce^{3+} , the $5d_1$ – $4f$ emission of Pr^{3+} at the dodecahedral Y site is low energy shifted with respect to perovskite host and shows the double peak band at $318 + 375$ nm. Pr^{3+} -doped LuAG scintillator characteristics were reported only very recently [50.160]. The $5d_1$ – $4f$ emission of Pr^{3+} is high energy shifted by about 0.12 eV and the onset of thermal quenching is shifted to noticeably higher temperatures (above 350 K) with respect to YAG:Pr. At RT, the photoluminescence and leading scintillation decay times are very similar (20 ns). The integral of the radioluminescence spectra in LuAG:Pr is 1.4–1.5 times higher than in LuAG:Ce, suggesting higher intrinsic scintillation efficiency. A spectrally uncorrected LY obtained in optimized Czochralski-grown crystal exceeds 300% that of BGO [50.161]. Another advantage consists in the negligible intensity of slower $4f$ – $4f$ emission lines in radioluminescence spectra in the 450–700 nm range for any Pr concentration, contrary to the situation found in YAG, YAP or LuAP matrices [50.122, 159, 160].

Among the point defects and extrinsic impurities studied in aluminum garnets it is worth mentioning the so-called *antisite* defects, F and F^+ centers (two and one electron in an oxygen vacancy, respectively), and iron impurity ions. Furthermore, recently in LuAG single crystals, the presence of Yb^{3+} was reported. Due to the variable charge state of iron ($\text{Fe}^{2+} \leftrightarrow \text{Fe}^{3+}$) it can easily participate in charge-carrier capture and give rise to a competing energy loss pathway. At higher concentrations (above 0.1%) Fe^{3+} is evidenced by a characteristic absorption doublet at 407 + 415 nm and a luminescence band around 800 nm [50.162]. At trace Fe concentrations, the lattice distortions due to embedding Fe^{3+} at the Al site were studied in detail by ESR. Presence of Fe^{3+} in the YAG lattice is also manifested through the charge transfer transition resulting in a wide absorption band at 255 nm [50.163] (Fig. 50.18). Also a Yb^{3+} ion can introduce additional nonradiative losses in LuAG:Ce scintillator as its charge transfer luminescence (similar in shape and about 0.14 eV high energy shifted with respect to that of YAP:Yb; Fig. 50.11) is heavily quenched at RT [50.164]. Fe and Yb ions come from the Al_2O_3 and Lu_2O_3 raw materials, and can be effectively detected by ESR [50.163, 165]. The paramagnetic Ce^{3+} ion in YAG was studied via ESR as early as the 1960s [50.166]. However, only very recently has the occurrence of Ce^{3+} ions at Al sites and possible space correlation between the regular Ce_{Lu} and Lu_{Al} antisite defect been reported in LuAG host [50.167, 168].

Oxygen-vacancy-based color centers are typical defects in aluminum garnets, because of the inert or even reducing atmosphere used during crystal growth. Such atmosphere is necessary to suppress the oxidation of the Ce^{3+} ion, which can decrease scintillator performance. Oxygen vacancies form deep electron traps; they can also effectively lower the scintillation efficiency of Ce-doped aluminum garnets. F^+ centers in YAG host show absorption bands at 235 and 300 nm (Fig. 50.18) and under excitation within these bands, F^+ luminescence was reported at ≈ 400 nm. Evaluation of polarization of this luminescence led to the proposal that F^+ centers might be perturbed by an adjacent Y_{Al} antisite defect [50.169]. Absorption bands at 240 and 200 nm were ascribed to F centers; excitation within these bands yields luminescence band at 460 nm [50.170]. The most studied defect in $\text{A}_3\text{B}_5\text{O}_{12}$ garnet structure (where A and B are trivalent cations), however, is the antisite defect created by an A cation occupying a B site and vice versa (Fig. 50.19). Such defects arise due to the presence of two equally charged cations and high growth temperature, which induces thermodynamical lattice disorder. In Ce (Pr)-doped aluminum garnets the A_{Al} ($\text{A} = \text{Y}, \text{Lu}$) one is of special importance (Fig. 50.19) as it gives rise to: (i) slower emission centers in the UV region, peaking at RT within 300–350 nm, which create an unwanted competitive de-excitation pathway in addition to Ce^{3+} (Pr^{3+}); (ii) shallow electron traps, which effectively delay the radiative recombination at the fast emission center and strongly degrade scintillator timing characteristics and LY value. These defects were detected by the existence of satellite $4f$ – $4f$ emission lines of RE^{3+} ions (Er^{3+} , Nd^{3+}) revealing an octahedral (rather than dodecahedral) emission site symmetry [50.171, 172]. Systematic study of characteristics of the mentioned UV emission has been published recently using time-resolved emission spectroscopy under synchrotron excitation [50.173, 174]. Direct comparison of the bulk single crystals with single-crystalline films grown by liquid-phase epitaxy (LPE) was made. Such films are grown at substantially lower temperature ($\approx 1000^\circ\text{C}$) and therefore are free of such defects. Moreover, it was shown in aluminum garnet structure that doping by trivalent ions of strongly different radius with respect to original cations, either at the dodecahedral or octahedral sites, induces new UV emission bands, i.e., an effect analogous to process (i). La or Sc doping are some of the most studied cases [50.175, 176]. Despite the easy doping and high overall scintillator efficiency achieved in the latter case, long decay times of this lumines-

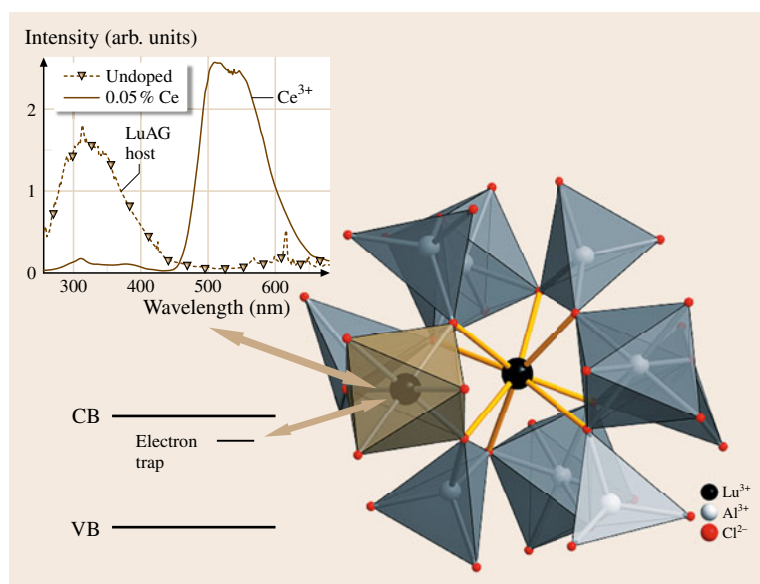

Fig. 50.19 The Lu_{Al} antisite defect in the LuAG structure. The resulting electron trap in the material forbidden gap is sketched on the left. The emission band within the range 300–350 nm due to the antisite defect and its competition with that of the Ce^{3+} center can be derived from radioluminescence spectra at RT (upper left). Emission lines around 312 nm and 615 nm in the undoped sample are due to Gd^{3+} and Eu^{3+} accidental impurities, respectively

cence (600–800 ns at RT) prevent practical application of such materials as fast scintillators.

It is worth noting, however, that in optimized YAG:Ce and LuAG:Ce bulk single crystals the residual UV emission contributes only a few percent to the total scintillation intensity, and no substantial energy transfer from the UV to Ce^{3+} band was found [50.158], so that the slowing of the scintillation response mentioned above is mainly due to the mechanism (ii), i.e., electron trapping at the antisite defect-related shallow traps before their radiative recombination at Ce^{3+} centers. In YAG:Ce, the TSL peak at 92 K was ascribed to such a trap, taking advantage of the comparison between a bulk single crystal and optical ceramics [50.140, 178]. In LuAG:Ce a comparison was made between a bulk single crystal and LPE-grown films [50.177]; the TSL structure within the 120–200 K interval was ascribed to such a trap (Fig. 50.20). Strong support for this ascription was obtained from TSL measurements of LuAG:Pr [50.179], where the glow curve below 250 K is found to be closely similar to that of LuAG:Ce, while TSL spectra are different, featuring the Pr^{3+} and Ce^{3+} emission spectra, respectively. Using the partial cleaning method, the thermal depth of the 92 K peak in YAG:Ce was calculated to be about 0.18 eV, while the triple TSL structure with peaks at 147, 169, and 187 K in LuAG:Ce was characterized by the energy values of 0.29, 0.40, and 0.47 eV, respectively. Deeper electron traps around the antisite defect and presumably higher concentration of these defects in LuAG with respect to

YAG result in a more severe delay in energy delivery to the Ce^{3+} centers in LuAG host and can thus explain the more severe LY degradation in the Lu-based garnet structure.

An interesting and technologically feasible possibility to decrease substantially trapping phenomena related to antisite defects in bulk crystals was recently announced. In mixed $\text{Lu}_3\text{Ga}_2\text{Al}_3\text{O}_{12}:\text{Pr}$ single crystal the TSL peaks in the 100–200 K temperature interval were completely suppressed, UV luminescence of the host disappeared at RT, and slower components and the

Fig. 50.20 TSL glow curves after x-irradiation at 10 K: comparison of LuAG:Ce LPE film and single crystal, see also [50.177]

α coefficient of scintillation decay were substantially lowered [50.179]. Even if the exact explanation of this effect has yet to be found, selective embedding of Ga^{3+} ions at octahedral lattice sites and related modification of the bottom of the conduction band due to lower-lying Ga-related energy levels [50.180] might be responsible for the observed effect.

Optimization of YAG- or LuAG-based fast scintillators by aliovalent ion codoping has not succeeded thus far. An attempt to codope LuAG:Ce with Zr^{4+} did not result in suppression of deep traps, at variance with what occurs in YAP:Ce [50.39, 144]. Deep traps related to 80 and 280 °C TSL peaks were markedly increased and only TSL peaks above 300 °C were suppressed [50.181]. It is interesting to note that recent atomistic simulations of defect creation in $\text{RE}_3\text{Al}_5\text{O}_{12}$ [50.182] point to a different response of the garnet lattice to tetravalent ion doping with respect to perovskite lattice [50.145, 146]. While in the latter case the production of interstitial oxygen was found as the least energy-requiring reaction, in the former case the production of RE cation vacancies seems to be the most energetically favorable process. Such a result may indicate that a different technological approach must be taken to improve aluminum garnet scintillators further.

50.2.4 Ce-Doped Silicate Single Crystals

The scintillation characteristics of Ce-doped rare-earth (RE) oxyorthosilicates were reported for the first time more than 20 years ago. After the first study, which revealed the promising properties of $\text{Gd}_2\text{SiO}_5\text{:Ce}$ (GSO) [50.183], numerous investigations were devoted to several other compounds of this material series, such as $\text{Lu}_2\text{SiO}_5\text{:Ce}$ (LSO), $\text{Y}_2\text{SiO}_5\text{:Ce}$ (YSO), $(\text{Y}_2)\text{-Lu}_2\text{Si}_2\text{O}_7\text{:Ce}$ (YPS and LPS), and several mixed compounds (most notably $(\text{Gd})_{2-x}\text{-Lu}_{2-x}\text{Y}_x\text{SiO}_5\text{:Ce}$; GYSO and LYSO, respectively). Single crystals were predominantly grown by Czochralski technique using an iridium crucible, which is necessary due to the very high melting point of these compounds (in the range $\approx 1950\text{--}2150$ °C). Radiofrequency (RF) induction heating was used in order to decrease the formation of polycrystalline regions, voids, and cracks [50.184, 185]. The optimization of all the manufacturing process enabled the growth of large single crystals (approximately 70–80 mm diameter and 200 mm length) with very good and reproducible scintillation performance [50.186–189]. Furthermore, material preparation in bulk, powders, and thin-film forms was pursued by other routes such as the pulling-

down technique [50.190], the sol–gel method [50.191, 192], and pulsed laser deposition [50.193]. In all cases promising scintillation characteristics were reported.

GSO possesses the monoclinic $P2_1/c$ crystal structure, while LSO and YSO possess the monoclinic $C2/c$ structure [50.194, 195]. The LSO structure is depicted in Fig. 50.21: it features SiO_4 tetrahedra and non-Si-bonded O atoms surrounded by four Lu atoms in a distorted tetrahedron. Band-structure and density-of-states calculations on YSO and YPS were recently performed [50.196].

In undoped crystals, in addition to intrinsic emission bands, further emission is clearly detected in the 250–400 nm region and interpreted as due to self-trapped excitons and holes [50.197]. Optical studies of Ce-doped samples showed two Ce^{3+} emission bands related to two different Ce^{3+} crystallographic sites in GSO, LSO, and YSO [50.198]. Due to its higher scintillation efficiency LSO was more thoroughly investigated; its PL spectra at 11 K are reported in Fig. 50.22 [50.199]. The doublet emission peaking at 393 and 427 nm was ascribed to Ce_1 whose luminescence is not quenched up to RT. On the other hand,

Fig. 50.21 The structure of LSO, with two Lu sites displayed and surrounding SiO_4 tetrahedra. Three oxygen ions with cut bonds form OLu_4 tetrahedra and do not participate in Si–O bonds

Fig. 50.22 Emission spectra of LSO at 11 K. The two emission spectra have excitation wavelength of 356 nm (solid line) and 376 nm (dashed line). Curves 1 and 2 refer to Ce_1 and Ce_2 centers, respectively (after [50.199])

the composite emission peaking at 460 nm, detected well only below 80 K, was ascribed to the Ce_2 center. The ionization processes of excited Ce^{3+} energy levels were studied by means of parallel photoconductivity and photoluminescence excitation–emission experiments [50.200], and by the microwave resonator technique [50.201], revealing three different delocalization processes of direct photoionization, tunneling, and thermal ionization of the lowest relaxed $5d_1$ level, found 0.45 eV below the conduction band.

The presence of two distinct Ce^{3+} emissions is in accordance with the existence of two Lu^{3+} crystallographic sites and with the substitutional incorporation of Ce for Lu.

Detailed information about incorporation of Ce^{3+} ions into Lu_2SiO_5 was obtained from ESR studies [50.202]. The g -value of a rare-earth ion is closely related to the wavefunction of its electronic ground state and therefore strongly depends on the point symmetry of the crystallographic site. Therefore ESR is indeed a good tool to investigate Ce^{3+} site symmetry and occupancy in crystal lattice.

Lu ions reside at two crystallographic sites with low (C_1) symmetry, Lu_1 and Lu_2 , with seven and six oxygen neighbors, respectively. Ce^{3+} ions are expected to substitute only for Lu^{3+} ions due to their similar ionic radii (Ce^{3+} : 0.103 nm; Lu^{3+} : 0.085 nm; Si^{4+} : 0.026 nm). ESR measurements support this assumption since Ce^{3+} ions are found at both lutetium sites. As the ESR intensity is directly linked to the concentration of para-

magnetic ions, the relative Ce^{3+} concentration in each site could be determined. The values are: $Ce_1 = 95\%$ and $Ce_2 = 5\%$. The most substituted site is attributed to the larger Lu_1 site with 6 + 1 oxygen neighbors. ESR spectra of LSO showing two Ce^{3+} resonance lines are shown in Fig. 50.23b. Moreover, in Fig. 50.23a the ESR spectrum of lutetium pyrosilicate ($Lu_2Si_2O_7$, LPS, with space group $C2/m$; see [50.203]) is also shown. In this case only one resonance signal is detected due to Ce^{3+} substituting for Lu^{3+} ion at the lone C_2 symmetry site.

In the $(RE)_2SiO_5$ material group, LSO presents the best figure of merit due to its highest density (7.4 g/cm³), short decay time (about 40 ns), high light output (about 3.5–4 times that of BGO), and satisfactory energy resolution (7.75%) [50.187]. Another important advantage is the absence of shallow traps, as indicated by the very low TSL intensity below RT [50.204], which is consistent with the absence of slower components in scintillation decay. On account of these characteristics, LSO found large-scale application, substituting for BGO in medical positron emission tomography (PET) systems [50.205]. Yttrium-admixed (several percent) LSO (LYSO) is an interesting alter-

Fig. 50.23a,b ESR spectra at 12 K of Ce^{3+} in (a) LPS and (b) LSO crystals with the magnetic field B parallel to the a -axis (after [50.102]) ($\pm 5\%$). The spectra were recorded at 9.5 GHz with a microwave power of 20 mW; modulation amplitude was 1 mT (after [50.202])

native to LSO because of its more favorable growth properties due to a lower melting point, lower formation of inclusions, lower cost of starting materials, and comparable or even better scintillation performance [50.186]. GSO has clearly inferior light output (Table 50.1) and scintillation decay also shows slower components. Recently, a positive effect of Zr codoping was reported, which increases its LY by about 20% [50.206]. Due to the lower density (6.7 g/cm^3) its attenuation length is 40% longer than that of LSO. However, its application in PET cameras is being considered as well [50.207].

In the case of LSO, it was soon recognized that it exhibits a fairly strong afterglow [50.209]. It consists of a light-emission signal which decreases exponentially following the end of an excitation pulse, and that can persist for several minutes up to hours at RT. This is a detrimental property of the crystal, since it causes background instability during repeated measurements.

Fundamental studies aimed at the comprehension of the microscopic physical mechanism governing afterglow were thus carried out in order to find possible technological solutions. The activation energy of the process was found to be approximately 1 eV [50.209]; the is in accordance with the calculated trap depth of a TSL peak at 375 K (using a heating rate of 6 K/s) so that afterglow appears to be due to RT carrier detrapping from the trap responsible for this peak followed by radiative recombination at Ce^{3+} luminescent centers. Actually the 375 K peak is the first of a series of as many as six peaks observed in the glow curve above RT, whose spectral emission coincides with the Ce^{3+} 5d–4f transition [50.209]. Annealing experiments in reducing or oxidizing atmosphere led to the suggestion that traps could be related to oxygen vacancies [50.210]. The presence of oxygen-related defects following irradiation was suggested from optical absorption measurements [50.211]; oxygen vacancies, together with STEs and STHs, were proposed to be responsible for TSL peaks below RT [50.197,212]. A very nice confirmation of the intrinsic origin of traps was the finding that all oxyorthosilicates possessing C2/c structure (YSO, LSO, YbSO, ErSO) are characterized by similar TSL glow curves above RT, irrespective of their doping [50.208, 211], so that crystal structure seems to play an important role in trap properties. In Fig. 50.24 the glow curves of LSO, LSO:Ce, YSO:Ce, and YbSO:Ce are compared. The favorable absence of afterglow in LPS, accompanied by the lack of TSL glow peaks close to RT [50.213], can thus be explained in terms of its different C2/m structure, leading to different

Ce^{3+} –oxygen (and thus oxygen vacancy) configurations and distances.

It is interesting to note that Pr^{3+} doping was also attempted in order to obtain a faster scintillation response of LSO-based scintillator. Fast Pr^{3+} 5d–4f photoluminescence has a maximum at 273 nm and decay time of about 6–7 ns at RT [50.214]. However, significant ionization of the 5d₁ relaxed excited state occurs at RT, because the 5d₁ level was found to be closer to the conduction band (0.28 eV) compared with the Ce^{3+}

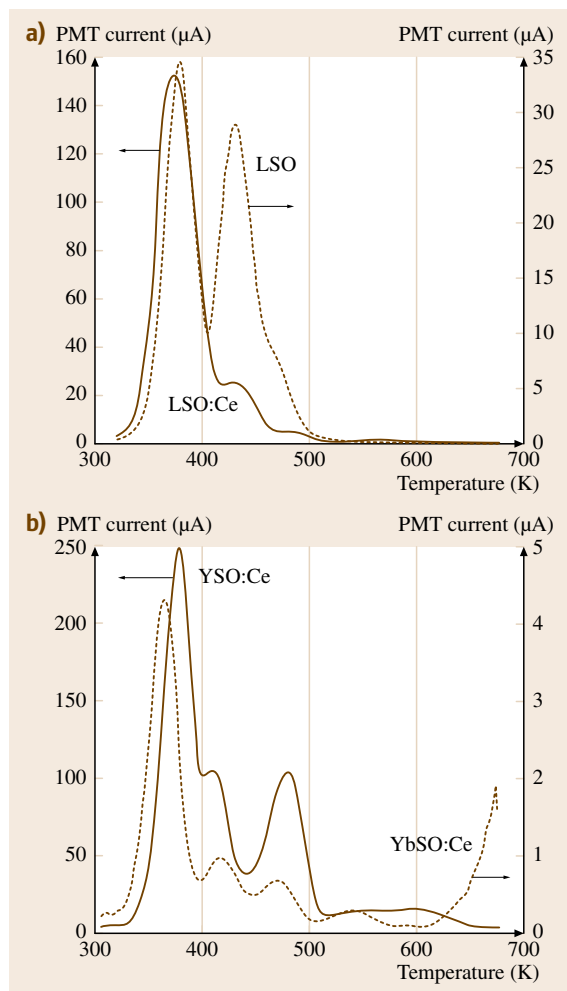

Fig. 50.24 (a) X-ray induced TSL glow curves of undoped and Ce-doped LSO taken by heating the samples at 5°C/s . (b) X-ray-induced TSL glow curves of YSO:Ce and YbSO:Ce. The sharp upturn above 650°C for the weak YbSO:Ce TSL is due to black-body radiation emanating from the silver sample holder (after [50.208])

center (0.45 eV). This ionization process significantly degrades **LY** values of LSO:Pr and prevents its practical application.

In conclusion, Ce-doped LSO, LYSO, and GSO proved to have excellent scintillating performances and are presently key materials for medical diagnostic **PET** applications; their further improvement should be based on better control of intrinsic point defects, especially those including oxygen vacancies.

50.2.5 Ce-Doped Rare-Earth Halide Single Crystals

During the last decade research on fast and efficient scintillators has found new very interesting candidates in the family of rare-earth (mostly La and Lu) halides. These are Ce-doped bromides, chlorides, and iodides

such as LaX₃:Ce and LuX₃:Ce, where X = Cl, Br or I. Some of their characteristics are listed in Table 50.2 where scintillation time decay, **LY**, and energy resolution are given for a specific Ce concentration.

Single crystals of Ce-doped rare-earth (**RE**) halides are usually obtained by vertical Bridgman growth technique using binary **RE** halides as starting materials. These starting materials can be prepared by several different routes [50.217, 223, 224]; for example, the preparation of **RE** iodides is performed by direct sealing of the metal with slight excess of iodine under vacuum in a silica ampoule, and heating up to the iodine melting point. On the other hand, the so-called *ammonium halide route* can be employed for the preparation of rare-earth chlorides and bromides. This process consists of two main steps. First, the dissolution of **RE** oxides in HCl or HBr with the addition of ammonium halide is

Table 50.2 Structural and optical characteristics of Ce-doped **RE** halides. Numbers in parenthesis in the scintillation decay time column represent the percentage of total intensity governed by the indicated decay time, while slower components characterize the decay of the remaining intensity. Times in parenthesis in the **LY** column represent the time gates with which the **LY** was evaluated. Original references are shown in square brackets

achieved

where M stands for the RE element (for instance La or Lu) and X stands for Cl or Br.

Subsequently, the ternary salt is heated under vacuum (typically up to 400 °C) and decomposed to obtain the final RE halide

Purification of the binary halides by sublimation under high vacuum is finally performed, allowing oxyhalides to be separated as involatile residues. The obtained powders can be used as starting materials for Bridgman growth. The crystals grown are highly hygroscopic. They must be sealed in appropriate ampoules for handling and characterization. Recently, Bridgman growth from commercially available anhydrous binary halide powders was performed and crystals with very good optical and scintillation characteristics were obtained [50.224].

While Pr^{3+} and Nd^{3+} doping of RE halides were considered for laser applications [50.226,227], only the Ce^{3+} ion appears to be suitable as a dopant of these

matrices to obtain fast and efficient scintillators. The radioluminescence spectra of Ce-doped samples are dominated by an intense 5d–4f Ce^{3+} emission. Other emissions related to the host crystal were detected as well. The assignment of such bands to specific centers and the study of their role in the energy transfer processes towards Ce^{3+} were soon the subject of systematic investigations. In this respect the most detailed study was performed on $\text{LaCl}_3:\text{Ce}$ [50.215, 216, 219, 225, 228, 229]. Figure 50.25 displays the x-ray excited emission of $\text{LaCl}_3:\text{Ce}^{3+}$ at different Ce^{3+} concentrations [50.225]. Apart from the Ce^{3+} doublet peaking at 337 and 358 nm, a shoulder attributed to STE emission is observed at about 400 nm. The excitonic nature of the 400 nm emission was established by an optically detected magnetic resonance investigation which revealed the existence of two excited triplet states attributed to *out-of-plane* STEs [50.230], one peaking at about 310 nm (superimposed to the Ce^{3+} emission) and the second at about 420 nm, similar to the shoulder seen in Fig. 50.25. On the other hand, no stable self-trapped holes (V_k centers) were found due to their immediate recombination with an electron from the conduction band resulting in STE state creation.

The mutual intensities of the Ce^{3+} and STE emissions are found to change with temperature (Fig. 50.26).

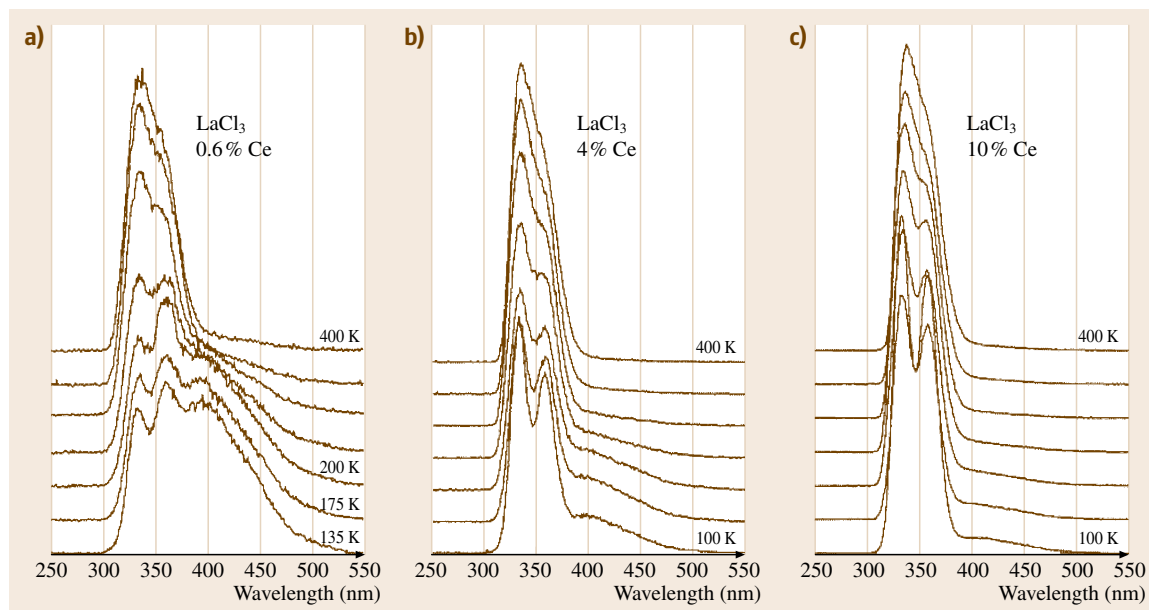

Fig. 50.25a–c X-ray excited emission in $\text{LaCl}_3:\text{Ce}$ as a function of temperature and Ce concentration: panel (a) 0.06% Ce; panel (b) 4% Ce; panel (c) 10% Ce. Unless otherwise indicated spectra are separated by 50 K temperature intervals (after [50.225])

Fig. 50.26 Temperature dependence of the Ce^{3+} , STE, and total luminescence in $\text{LaCl}_3:0.57\% \text{Ce}$, derived from x-ray-induced emission spectra. The error bars are comparable with the dimensions of the data points (after [50.215])

Namely, STE emission decreases for $T > 200 \text{ K}$, while an opposite dependence is detected for the Ce^{3+} 5d–4f transition. The anticorrelation between STE and Ce^{3+} luminescence was interpreted by assuming the occurrence of energy transfer towards Ce^{3+} ions through STE diffusion. Specifically, soon after irradiation, thermalized electrons and holes form STEs, which can migrate and be trapped at Ce sites before their radiative de-excitation. STE mobility increases with increasing temperature in accordance with the observed temperature dependences in Fig. 50.26 [50.229]. The nonexponential character of the Ce^{3+} scintillation time decay [50.215, 229] was interpreted as due to the existence of two energy localization mechanisms at Ce^{3+} sites, namely (i) prompt trapping of holes and electrons by cerium ions, leading to a fast decay component determined by the intrinsic cerium 5d–4f emission lifetime, and (ii) the above-mentioned thermally assisted energy transfer from STE to cerium ions, leading to a slow scintillation decay governed by STE lifetime in the microsecond timescale. Room-temperature STE lifetime ($3.5 \mu\text{s}$) was derived from the scintillation time decay of an undoped LaCl_3 sample [50.229]. Moreover, a possible role of defects acting as trap levels in the slow scintillation decay processes was taken into account. Such trap levels were investigated in a few TSL studies [50.231, 232]. These studies showed the presence of several TSL peaks in LaCl_3 and LaBr_3 both below and above RT. However, TSL properties have not yet been clearly correlated with slow decay components.

Fig. 50.27 Scintillation decay time spectra of (a) $\text{LaBr}_3:0.5\%\text{Ce}$ and (b) pure LaBr_3 at RT under ^{137}Cs γ -ray excitation. The decay of the doped sample is approximately single-exponential with decay time of 30 ns. The faster component in the decay of pure LaBr_3 is probably due to Ce^{3+} trace impurities; the longer component is due to STE luminescence. The inset shows the spectrum of $\text{LaBr}_3:0.5\%\text{Ce}$ on a shorter time scale (after [50.233])

The best scintillation performances in terms of LY, decay time, and energy resolution are displayed by $\text{LaBr}_3:\text{Ce}$ [50.218, 233, 234]. In Fig. 50.27 scintillation time decay spectra of $\text{LaBr}_3:\text{Ce}$ are shown, which feature a fast and approximately single exponential component. In this crystal, efficient direct energy localization at Ce^{3+} ions occurs and an intermediary role of STE migration processes seems to be not relevant, probably due to the shorter STE decay time and higher STE migration rate evidenced in bromides with respect to chlorides [50.219]. Moreover, a higher number of electron–hole pairs are generated with respect to LaCl_3 due to a smaller bandgap (Table 50.2), resulting in a very high LY of 70 000 phot/MeV.

Even smaller bandgap, shorter STE decay time, and higher STE migration rate characterize the heaviest iodides [50.219]. However, other drawbacks arise in the case of $\text{LaI}_3:\text{Ce}$. For example, the small bandgap value and the small energy difference (0.1–0.2 eV) between the position of the Ce 5d level and the bottom of the conduction band seem to be responsible for its very poor scintillation properties at RT [50.220]. At $T > 120 \text{ K}$ 5d electrons can be thermally activated to the conduction band and luminescence becomes quenched. A more favorable situation is encountered in the case of LuI_3 [50.221, 222, 235] due to the slightly higher bandgap value and longer emission wavelength, so that

the energy difference between the Ce^{3+} 5d level and the conduction band is greater. Thermally activated transition into the conduction band does not occur and a quite high LY (70 000 phot/MeV, Table 50.1) was reported. Optimization of $\text{LuI}_3\text{:Ce}$ is still needed as it presently shows intense slow decay components; moreover crystal inhomogeneities were also reported [50.222].

In conclusion, Ce-doped RE halides constitute a very interesting material group in which scintillation properties vary strongly due to slightly different microscopic properties. At the present time $\text{LaBr}_3\text{:Ce}$ possesses the best scintillator performances, due to a favorable combination of STE lifetime, STE migration rate, bandgap value, and position of Ce^{3+} energy levels in the forbidden bandgap.

50.2.6 Optical Ceramics and Microstructured Materials

Optical ceramics are transparent or translucent materials constituted by tight aggregating crystallite micrograins, each randomly oriented with respect to its neighbors. They have been under development as an alternative to single-crystal materials to provide bulk optical elements in the case where single crystals cannot form or when ceramic materials show superior properties, for example, in terms of achievable concentration or homogeneity of the dopant. The associated technology has developed greatly, mainly within the last two decades; in the case of cubic material, technological progress enabled bulk elements that were visually indistinguishable from single crystals and in terms of some parameters (doping profile) even clearly superior. Among the developed materials, mainly YAG:Nd and $\text{Y}_2\text{O}_3\text{:Nd}$ reached the highest degree of perfection; their primary application is in the field of solid-state lasers [50.236, 237]. The size of the single-crystal grains is on the order of a few tens of microns, interface thickness is reported to be only about 1–2 nm, and the residual volume of pores is several ppm.

It is worth noting that the application demands are clearly higher in the case of scintillators compared with laser optical ceramics. In the latter case the scattering losses due to pores (voids) and grain interfaces limit the material performance. The already achieved reduction of the pore volume down to a few ppm and interface thickness to a few nm reported in [50.236, 237] is enough to make them fully comparable to their single-crystal analogs. However, in the case of scintillators, even point defects at the atomic scale can seriously limit material performance due to the introduction of

trapping levels in the material forbidden gap. If we consider a grain size on the order of a few tens of μm and thickness of the interface layer of 1–2 nm, the expected concentration of the interface-related (trapping) states may easily reach several hundred ppm. Such a concentration can noticeably influence the characteristics of the transport stage due to retrapping of the migrating carriers or even the introduction of nonradiative traps, which can seriously degrade the scintillation response and/or overall efficiency parameters.

Development of optical ceramics for scintillator applications was triggered by the needs of computer tomography (CT) medical imaging. A review of the results achieved, mainly for the manufacturing and characterization of $(\text{Y,Gd})_2\text{O}_3\text{:Eu}$, $\text{Gd}_2\text{O}_2\text{S:Pr,Ce,F}$, and $\text{Gd}_3\text{Ga}_5\text{O}_{12}\text{:Cr,Ce}$ ceramics, was reported by Greskovich and Duclos [50.238]; see also [50.239–241] for more details about the particular materials. In the latter two materials, codoping with Ce^{3+} is used to reduce the afterglow through the capture of holes at Ce ions, $\text{Ce}^{3+} \rightarrow \text{Ce}^{4+}$ conversion, and subsequent nonradiative recombination with migrating electrons and/or temporary Eu^{2+} centers. Moreover, codoping of $(\text{Y,Gd})_2\text{O}_3\text{:Eu}$ [50.242] with Pr^{3+} appeared to be an efficient tool to reduce the afterglow (by a mechanism similar to that of the Ce ions above). Annealing in a controlled atmosphere can further diminish or passivate trapping states in the forbidden gap related to the grain interfaces. Eu^{3+} - or Tb^{3+} -doped Lu_2O_3 are worth mentioning among new optical ceramics suggested for scintillator applications and based on the slow 4f–4f transitions of rare-earth ions. True optical ceramic $\text{Lu}_2\text{O}_3\text{:Eu}$ samples were synthesized, their performance was tested in comparison with CsI:Tl , and a large-area scintillation screen was prepared [50.243, 244]. While providing 60% of the emission intensity of CsI:Tl , a better match to the CCD photodetector sensitivity was concluded. Unfortunately, $\text{Lu}_2\text{O}_3\text{:Eu}$ was found to suffer of noticeable afterglow for times longer than 6 ms [50.245].

Recently, fast and potentially less expensive optical ceramics based on Ce-doped YAG have been reported in the literature [50.246]. Nowadays, Ce-doped YAG optical ceramics are available from Baikowski, Japan Ltd., the production technology of which should be analogous to that of YAG:Nd described in [50.236]. Figure 50.28a,b shows a comparison of radioluminescence and scintillation decay characteristics in equally shaped samples ($\varnothing 15 \times 1$ mm) of an industrial standard-quality single-crystal YAG:Ce produced by CRYTUR, Ltd., Czech Republic and the aforementioned opti-

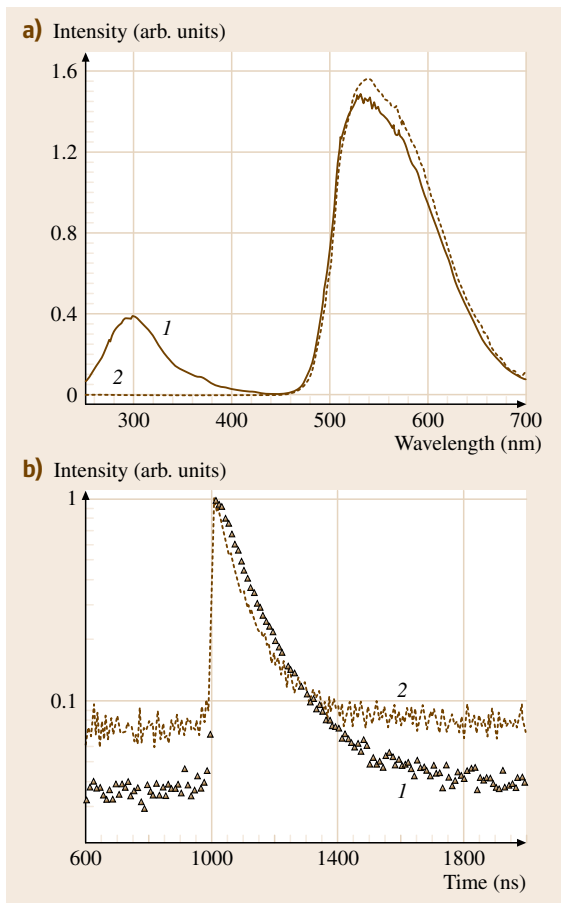

Fig. 50.28 (a) Radioluminescence spectra (Mo cathode, 35 kV) of **YAG:Ce** single-crystal (1) and ceramic (2) scintillators at room temperature. (b) Spectrally unresolved scintillation decay of **YAG:Ce** single-crystal (1) and ceramic (2) scintillators at RT, with excitation by 511 keV photons of ^{22}Na radioisotope. Approximation by a sum of exponentials yields decay time of 119 ns (1) and 85 ns (2) for the dominant component

cal ceramics [50.140]. While the radioluminescence intensity in the Ce^{3+} band at 550 nm is comparable in both samples (Fig. 50.28a), the host 300–350 nm band is absent in the ceramic sample. This UV emission is ascribed to a luminescence center based on an antisite Y_{Al} defect (Sect. 50.2.3) and its formation is crucially dependent on the preparation temperature. As the preparation temperatures of **YAG**-based optical ceramics are noticeably lower with respect to the single crystal [50.236], it can be concluded that the Y_{Al} anti-

site defects are absent in the former system. Normalized scintillation decays are shown in Fig. 50.28b. The ceramic material shows faster decay in its initial part, the decay time of which is closer to the photoluminescence lifetime of the Ce^{3+} center (about 60–65 ns). This can be explained by a higher Ce concentration and the absence of Y_{Al} antisite defects. However, a higher content of very slow scintillation components is reflected in lower amplitude-to-background ratio. The presence of such very slow decay components is usually related to traps monitored by TSL measurements somewhat below RT. Indeed, the ceramic system shows higher TSL intensity above approximately 190 K [50.140], possibly due to the presence of traps at the grain interfaces. Recently, also **LuAG:Ce** optical ceramics were prepared by a coprecipitation route [50.247] (Fig. 50.29) and the scintillation performance was compared with that of **LuAG:Ce** single crystal [50.248]. Similar to

Fig. 50.29a,b Scanning electron microscopy (SEM) photographs of **LuAG:Ce** ceramics sintered at 1800 °C for 10 h under vacuum: (a) the fracture surface; (b) the polished surface after thermal etching at 1400 °C for 1.5 h [50.247] (courtesy of Xue-Jian Liu, Shanghai Institute of Ceramics)

YAG:Ce optical ceramics, high radioluminescence efficiency was found. However, noticeably lower **LY** and the presence of more intense slow components in the scintillation decay point to retrapping phenomena at the grain interfaces, which is supported also by measured **TSL** characteristics.

Microstructured materials can be classified as single-crystal-based systems grown with tailored spatial morphology. These materials were developed to meet the demand of increased x-ray absorption, while keeping high spatial resolution in the x-ray imaging screens. Few scintillation materials, namely **CsBr:Tl** [50.249], **CsI:Na** [50.250], and **CsI:Tl** [50.251–253], can be prepared by vacuum evaporation in the form of long (up to 1–2 mm) and thin (several μm diameter) needles, which are densely packed and optically isolated (Fig. 50.30). A needle layer can be directly deposited on the photodetector and, due to the light-guiding effect in the needles, the high spatial resolution is preserved with increased layer thickness, ensuring higher x-ray absorption. While this concept has been used for a long time for **CsI:Na** in image intensifiers [50.254], where the **CsI:Na** is at the inner side of the photocathode, i.e., in vacuum, it could not be used in the open atmosphere due to its extreme hygroscopicity. Only the development of this growth morphology for much less hygroscopic **CsI:Tl**, and the availability of large-

Fig. 50.30 Vapor-deposited column-shaped **CsI:Tl** scintillation crystals of very smooth structure. Diameter $\approx 3 \mu\text{m}$, length $> 0.5 \text{ mm}$; see also [50.20] (courtesy of Philips Research Laboratories, Aachen)

area position-sensitive semiconductor detectors (**CCD**, **a-Si:H** panels) enabled the construction of a new generation of flat-panel detectors, which provide a qualitative upgrade in many kinds of medical, industrial, and scientific imaging systems [50.255].

50.3 Future Prospects

Acceleration of research and development in the field of scintillation materials over the last 20 years has been motivated mainly by new demanding applications in the medical, industrial, scientific, and security imaging sectors. Further development and exploitation of powerful x-ray sources, e.g., synchrotron radiation, the availability of new radiopharmaceuticals significantly enhancing **PET** imaging capability in oncology [50.256], and the wider exploitation/monitoring of radioisotopes in different branches of human activity continue to contribute to increasing interest in fast and efficient scintillators.

Currently, there is a need for high-density, fast, and high-light-yield scintillators for **PET**. While **LSO:Ce** and **GSO:Ce** were successfully introduced and are replacing the previously used **BGO** [50.205–207] the search for a second material to be used in combined **PET** detectors to correct for the depth-of-interaction error continues [50.257]. Furthermore, in **PET** detectors

sufficiently fast and bright **Ce-** or **Pr-doped** materials enable evaluation of time-of-flight information related to the coincidence detection of two 511 keV photons from the rising edge of the scintillation decay. Such information can limit the number of random coincidences and increase the signal-to-noise ratio [50.258]. The candidates are **(Lu/Y)AP:Ce** or **LuAG-based** scintillators, which are under intense investigation. Undoubtedly, all of these materials could be further improved since the nature of defects participating in the scintillation conversion and degrading their performance is not yet fully understood.

As the majority of applications use x-ray sources with energies below 150 keV, there is significant market potential for very high light yield, medium density, fast scintillators, where the latest developments led to the discovery of the group of **Ce-doped rare-earth halides**. Also in this case, understanding of material point defects is at the early stages and improve-

ments in crystal quality are expected in the near future.

The rapidly developing field of optical ceramics may bring completely new material systems into consideration, which cannot be prepared in the form of single crystals. The recent success of slow scintillation ceramics based on Tb^{3+} -, Eu^{3+} - or Pr^{3+} -doped materials in CT medical imaging has clearly shown the potential of this manufacturing technology. Even in the case of YAG:Ce or LuAG:Ce materials, which can be relatively easily grown in single-crystal form, optical ceramics may offer an interesting alternative due to the absence of specific (e.g., antisite) defects, which degrade scintillation performance of the single crystal. On the other hand, one should keep in mind that grain boundaries and interfaces in the ceramics introduce other trapping states with undesirable consequences as described in Sect. 50.2.6.

It is interesting to mention recent literature reports dealing with phosphors prepared from materials of smaller bandgap (sulfides, selenides, tellurides) due to their expected higher conversion efficiency. In these materials the emission center can be based on an exciton localized close to a suitable doped impurity ion. Very high efficiency and decay time of about 1 μs at RT were reported for ZnTe:O [50.259]. Apart from the powder form, these materials can be prepared in the form of thin films as well using a novel sol-gel technology, which offers better controlled synthesis conditions and more perfect microcrystal grain surfaces. Thin-film scintillators were developed for special applications requiring high two-dimensional (2-D) resolution in monitoring tiny objects. High-quality single-crystalline films can be grown by liquid-phase epitaxy technique, which was demonstrated in the case of YAG and LuAG-based scintillators [50.260, 261] or ZnO [50.262].

Renewed interest in the scintillation characteristics of direct-bandgap semiconductors based on ZnO or other binary compounds has arisen recently [50.30, 31, 263] due to their superfast emission with decay times below 1 ns. Emission in these materials is due to Wannier excitons, free or localized at defects/doped ions. In the latter case it shows a low energy shift and still faster decay times of the order of tens of picoseconds.

Donor-acceptor recombination luminescence in suitably doped systems was also reported [50.264]. Such materials can show an unbeatable combination of superfast scintillation response and (intrinsically) high light yield. The problem of low Stokes shift and en-

Fig. 50.31 RT photoluminescence decay of ZnO:In, Li liquid-phase epitaxy grown film. $\lambda_{\text{exc}} = 260$ nm, 150 fs laser pulse, $\lambda_{\text{em}} = 420\text{--}430$ nm. The solid line shows the $I(t)$ dependence proportional to inverse time typical of donor-acceptor pair recombination luminescence

hanced emission reabsorption in bulk elements might be solved by the aforementioned exciton localization or exploitation of fast donor-acceptor recombination luminescence (Fig. 50.31) [50.32]. A new class of so-called *quantum scintillators* based on quantum dots (nanostructures) of direct-gap semiconductors embedded in a suitable host was announced recently [50.265, 266]. These materials exploit a quantum size effect in free exciton emission, which can enhance the efficiency and luminescence speed in such nanostructured materials with respect to the bulk analogues.

A separate group of scintillation materials is under development for neutron detection. These materials must contain elements with high cross-sections for neutron capture (^6Li , ^{10}B , $^{155,157}\text{Gd}$) and ideally should have a low effective Z-number, rendering them insensitivity to γ -rays. These constraints substantially limit the number of candidate material compositions [50.267]. Such scintillation detectors are needed in new safety precautions to be employed at airports, seaports, and country borders to defend against terrorist activities and to detect illicit trafficking or inadvertent circulation of nuclear materials or radioactive sources and chemical warfare agents. Development of such monitoring portals is conditional on the availability of sufficiently intense portable neutron sources, which are under development as well.

50.4 Conclusions

In this chapter the broad field of scintillation materials has been introduced, albeit limited to selected single-crystal groups, optical ceramics, and microstructured materials. The variety of materials considered or currently under development is due to the range of demands of the ever-growing number of practical applications and the need to tailor scintillation materials to each of them.

Attention was paid not only to listing the materials and their scintillation characteristics, but also to addressing the issue of specific material defects and their relationship with the manufacturing technology used. Material defects and irregularities often give rise to energy levels in the host forbidden gap. Such energy levels can constitute trapping states, which serve as centers of nonradiative recombination or simply as delaying ele-

ments in the process of energy transport to the emission centers. Consequently, both the scintillator efficiency and timing characteristics are degraded. Understanding the underlying physical mechanisms of energy transfer and storage and the role of particular material defects is of crucial importance for bringing material performance close to the intrinsic limits. The necessity to use correlated experiments based on time-resolved spectroscopy, thermoluminescence, and magnetic resonance to understand the nature of defects has been demonstrated in several examples.

Finally, it is worth noting that another area of progress in the realization of advanced detector design concerns the rapid development of the field of semiconductor photodetectors, which are an indispensable part of scintillation detectors.

Silicon Solar

51. Silicon Solar Cells: Materials, Devices, and Manufacturing

Mohan Narayanan, Ted Ciszek

The phenomenal growth of the silicon photovoltaic industry over the past decade is based on many years of technological development in silicon materials, crystal growth, solar cell device structures, and the accompanying characterization techniques that support the materials and device advances. This chapter chronicles those developments and serves as an up-to-date guide to silicon photovoltaic technology. Following an introduction to the technology in Sect. 51.1, an in-depth discussion of the current approaches to silicon material crystal growth methods for generating solar cell substrates is presented in Sect. 51.2. Section 51.3 reviews the current manufacturing techniques for solar cell devices and also presents the latest advances in device structures that achieve higher efficiency. Finally, a perspective on the technology and what might be expected in the future is summarized in Sect. 51.4.

51.1 Silicon Photovoltaics

Solar cells convert sunlight into electricity via the photovoltaic effect. The photovoltaic (PV) effect was first reported in 1839 by Becquerel when he observed a light-dependent voltage between electrodes immersed in an electrolyte. However, nearly a century later in 1941, the effect was reported in silicon. In 1954, the first working solar cell module was announced. The photovoltaic industry has grown from producing a few kW in the 1960s to a multi-GW production in this decade. The success of the industry is mainly due to its ability to supply reliable and modular power, cost effectively, from a few W to multi-MW. With the market growing by nearly 20% per year for the past 10 years, the amount of silicon used in the PV industry is poised to be

significantly more than that used in the semiconductor industry in this decade.

51.1.1 Physics of a Solar Cell

When incident sunlight (photon) is absorbed by a semiconductor, photon energy is transferred to the material. If the absorbed photon has sufficient energy, interband transition occurs and an electron is excited from the valance band into the conduction band. The valance state vacated by the electron is called a hole. The free electrons generated flow freely inside the material and can be drawn to the external world to be used as electricity.

The solar radiation spectrum can be broadly divided into three portions: (1) infrared, (2) visible, and (3) ultraviolet. The long-wavelength, infrared portion of the sun spectrum does not have the threshold energy needed to free electrons from silicon atoms and passes through the cell without interacting. The material is transparent to these long wavelengths. The ultraviolet (short-wavelength) portion of the sun spectrum has more than enough energy to create the electron-hole pairs. In the case of silicon, with a bandgap of 1.1 eV at room temperature, only photons with energy greater than 1.1 eV will exhibit the PV effect. The excess energy transferred to the charge carriers is dissipated as heat. Hence, only about 40% of the incident light energy is effectively used. The irradiance spectrum is an important consideration in designing solar cells, as solar cells respond differently to photons of different energy. The spectrum of sunlight changes continually as a function of time of the day, weather, and location. Solar cells are exposed to different spectra and hence need to operate under a variety of irradiances.

The solar cell is a p-n junction, like a large-area diode with metal contacts on either side, as illustrated by Fig. 51.1. The n-type portion (typically near the front of the device) has a high density of electrons and few

Fig. 51.1 Operation of a silicon solar cell (after [51.1])

holes, so generated electrons can travel easily in this region. The opposite is true in the p-type region, where holes travel easily. The built-in electric field near this junction of n- and p-type silicon causes photogenerated excess electrons to wander toward the grid on the front surface, while the holes wander toward the back contact. The electrons generated far away from the junction in the bulk tend to diffuse towards the junction if they are within the influence of this built-in electric field.

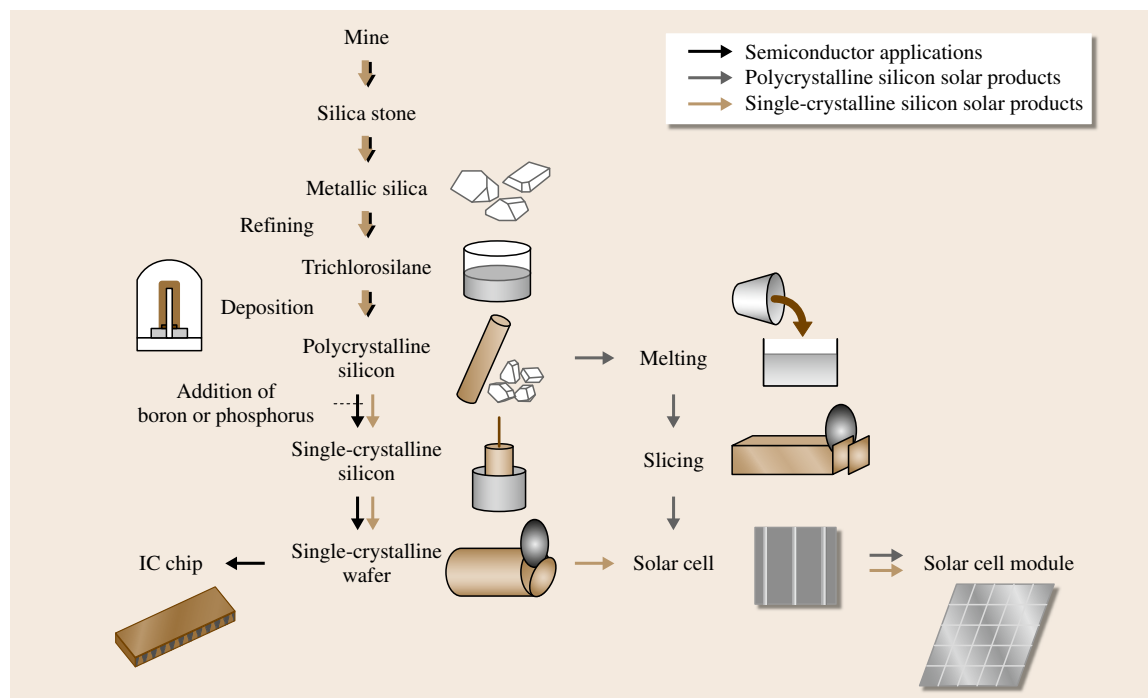

Fig. 51.2 PV silicon value stream (after [51.2])

Fig. 51.3 (a) Series connection of solar cells. (b) Components of the PV module (after [51.7])

If the electrons survive their trip across the cell thickness, without recombining at defects or impurities, they are collected at the grid. Then they flow through an external circuit as current that can operate an electronic instrument or appliance. After that, they reenter the solar cell at the back contact to recombine with holes and the process repeats [51.3–6].

51.1.2 The Photovoltaic Value Chain

More than 80% of manufactured solar cells are based on a crystalline silicon (single-crystalline or multicrystalline) substrate. The value stream of the photovoltaic industry is shown in Fig. 51.2 [51.2].

High-purity polysilicon (produced by the conventional Siemens polysilicon process or by a fluidized bed process) along with recycled silicon is the dominant feedstock for the PV industry. Due to increased demand for PV systems, several programs to upgrade metallurgical-grade silicon are also being actively pursued. The feedstock is then converted into silicon wafers by casting or crystal growth followed by a wire-sawing process. Details of this process step are described in Sect. 51.2. The silicon substrate is converted into solar cells using technologies based on semiconductor device processing and surface-mount technology (SMT). The cell process technology (Sect. 51.4) mainly consists of wafer surface etching, junction formation, antireflection coating deposition, and metal contact formation. The individual solar cells are connected and assembled into the finished product: PV modules, which are integrated with system components, inverters, charge

conditioners, batteries etc. and then installed at the site.

The crystalline silicon wafer accounts for about 40% of the cost of a PV module. There have been ongoing efforts to reduce the cost of PV modules: the use of thinner substrates to save the cost of silicon used, device research to increase the conversion efficiency of the module, high-volume manufacturing with inline process control to reduce the cost of manufacturing, etc.

51.1.3 The Photovoltaic Module

The PV module is designed to generate electricity for many years (usually more than 25 years). It has to operate over a wide range of daily and seasonal variations of sunlight and weather. It must be mechanically rigid to provide a means for mounting the module into its service structure. It must be dielectrically rigid in order to protect living beings from coming into contact with dangerous electrical voltages, as well as to prevent system failure through short circuit.

The photovoltaic module (as shown in Fig. 51.3a,b) consists of a number of solar cells electrically connected to each other with metal interconnects and supported by a rigid superstrate. The interconnected cells are encapsulated by one or more layers of polymeric materials like ethyl vinyl acetate (EVA) and Tedlar, which provide electrical insulation. The encapsulation provides mechanical rigidity to the brittle cells and the flexible interconnection. In addition, it offers chemical protection as a moisture barrier. The encapsulated cell

assembly, called a laminate, is then attached to a tempered, low-iron glass superstrate. An electrical junction box is provided at the rear of the module to harness the electricity generated by the module.

51.1.4 Commercial PV Technologies

The commercial success of PV is largely due to the proven reliability and long lifetime (> 25 years) of crystalline silicon modules. Accelerated environmental testing, based on correlation of the specific failure mechanism with outdoor field test results, is used to certify the module performance in the field. If the module passes the environmental tests it will likely perform reliably for more than 20 years.

More than 85% of all modules sold today are based on crystalline-silicon solar cells. Several factors have

contributed to the choice of crystalline silicon: high cell conversion efficiencies of 15–20%; availability of commercial equipment from the semiconductor and SMT industries; extensive volume of knowledge on silicon device physics, established feedstock technologies, abundant supply of the source material (sand), etc. Other PV technologies include devices based on amorphous silicon (a-Si), cadmium telluride (CdTe), copper indium diselenide (CIS), and gallium arsenide (GaAs). While a-Si-based devices suffer from lower efficiencies, devices based on GaAs and CdTe have shown high conversion efficiencies. However, the high cost of the material, scarce raw material availability, and toxic nature of the process and material are major challenges facing these technologies for multi-GW manufacturing. Here, only silicon-based PV issues will be discussed in detail.

51.2 Crystal Growth Technologies for Silicon Photovoltaics

51.2.1 Silicon Photovoltaics

The history of crystalline and multicrystalline silicon growth for PV applications starts with, and is closely aligned with, the methods utilized in the semiconductor industry. From the first solar cell produced at Bell Labs in 1954 [51.8] on Czochralski (CZ)-grown silicon through to the development of modern high-efficiency cells, the prominent integrated circuit (IC) industry crystal growth methods have served the PV industry well. The highest-efficiency PV cells and modules commercially available today continue to use the CZ method and, to a lesser extent, the float-zone (FZ) method.

Early in IC development, it was realized that elimination of ingot wafering held many advantages, including simplified surface preparation, thinner wafers, and improved feedstock utilization. The dendritic web Si ribbon growth method, originated in 1962 [51.9], was briefly explored commercially by Dow Corning Corporation in the mid 1960s with an eye toward IC use as well as applications in the fledgling PV industry. Despite more than 30 years of development for PV use, largely by Westinghouse, the web method ultimately proved nonviable for PV production throughput needs in the rapidly growing PV industry. When Tyco Laboratories announced the growth of shaped sapphire crystals by the edge-defined film-fed (EFG) method in 1971 [51.10], Dow Corning researchers quickly realized that this method might also be useful for PV and

they published the first growth of silicon ribbons by EFG, using graphite capillary dies, in 1972 [51.11]. A few years later, in 1975, researchers at IBM published the first growth of silicon tubes by EFG [51.12] for potential application as the active, internally cooled, PV receiver in linear parabolic concentrators. The closed tubular shape eliminates edge instability problems and is easier to grow than ribbons. The later, larger, hybrid consisting of a closed tubular shape, but with multiple flat walls, is the current EFG production method for PV wafers. The wafer blanks are laser-cut from the flat tube walls. While dendritic web growth produces single-crystal ribbon surfaces, EFG growth yields multicrystalline wafers.

The dendritic web method, in a sense, spawned another multicrystalline ribbon growth method in which foreign filaments replace the continuously propagating edge dendrites. This simplifies thermal control considerably. The method was introduced as edge-supported pulling (ESP) [51.13] in 1980, using carbon-based edge filaments incorporated into the growing ribbon. After many years of dormancy, it was resurrected by Evergreen Solar as string ribbon. The string ribbon and flat-sided tubular EFG growth methods are in use today and have made strides in improving throughput by effectively increasing the width of material grown in a single apparatus through multiple wide faces (EFG) and multiple ribbons (string ribbon). This was not possible with the more complex dendritic web growth

method. Another class of silicon sheet growth methods that we will include in this discussion, although there is currently no large commercial application, is that in which the sheet moves rapidly in a direction orthogonal to the direction of heat removal. This class of growth methods has shown remarkable throughput potential (more than 40 MW of PV wafer material per machine per year), but so far has suffered from relatively large sheet thickness, small grain size, high impurity content, and low cell efficiencies.

Casting of multicrystalline silicon shapes has been conducted for over 80 years. In the mid 1970s, attention was turned to this method as a way of producing PV wafer material. Fischer and Pschunder reported casting of silicon into graphite molds for PV applications [51.15] in 1976. The technique of melting and then resolidifying silicon in the same graphite container (thermal expansion-matched to silicon), with bottom seeding, was introduced in 1979 [51.16]. Multicrystalline ingot growth has become the dominant method for PV wafer production and is most often conducted by melting and then directionally solidifying (DS) the Si material in the same silicon-nitride-coated, silica-based, square crucible with small height-to-width aspect ratio. This allows more columnar growth than taller crucibles. One semicontinuous multicrystalline ingot casting method introduced in 1985 [51.17,18] uses electromagnetic repulsion to keep silicon from adhering to water-cooled metal finger walls. Electromagnetic casting (EMC) currently produces > 2000 kg silicon ingots at a much higher throughput rate than conventional directional solidification in silica crucibles.

We will consider the above silicon growth methods that are presently in use for PV wafer manufacturing in the following sections. The categories include single-crystal ingots, multicrystalline ingots, and multicrystalline ribbons or sheets.

51.2.2 Single-Crystal Ingot Growth (CZ and FZ)

Since CZ growth is the main silicon growth method of the IC industry, it is quite well documented in other literature, and we need not go into it in detail here. A basic schematic of the process is shown in Fig. 51.4, along with one for FZ growth. Here we will focus primarily on the aspects of growth pertinent to PV applications. CZ and FZ ingots are round, so the active area of a module relative to the total area is lower than for cast or ribbon wafers, unless the ingots are trimmed to a square or rounded-square cross-section. For optimum perfor-

Fig. 51.4a,b Schematic of CZ (a) and FZ (b) crystal growth (after (a) [51.14], (b) [51.1])

mance, the ingots must be both single crystalline and dislocation free. Multicrystalline CZ or FZ ingots are more highly stressed than cast multicrystalline ingots, and the grain boundaries are more electrically active, resulting in poorer cell efficiency. If ingot growth is initiated single crystalline but not dislocation free, the ingots soon become multicrystalline (an exception is the special case of using a tricrystalline seed [51.19]). The requirement for dislocation-free growth means that care must be taken to avoid particulate matter, high impurity levels, sudden thermal changes, and other perturbations that could disrupt dislocation-free growth. Impurities in CZ growth (and in directional solidification of multicrystalline ingots) obey the normal freezing equation, $C/C_0 = k(1 - f)^{k_0 - 1}$, if there is thorough mixing in the liquid. C is the impurity concentration in the ingot where a fraction f of the melt has been solidified, and k is the effective segregation coefficient of the impurity (always less than the ideal segregation coefficient k_0); C_0 is the initial average impurity concentration in the melt before solidification commences. Impurity segregation is quite effective in the early-grown portion of the ingot where $C \approx kC_0$, but impurity concentrations rise monotonically to levels $> C_0$ near the termination of growth, as shown in Fig. 51.5. Boron hardly segregates at all, since $k \approx 0.9$. This is advantageous for giving a flat doping profile along the ingot, but it also dictates that no excess boron can be present in the feed-

Fig. 51.5a,b Distribution of selected impurities as a function of ingot fraction solidified for CZ or directional solidification carried out in near-atmospheric pressure (a) and in vacuum (b) (after [51.14])

stock, since it cannot be removed by segregation during growth.

The vapor pressure and hence the effective evaporation coefficient of a particular impurity also can affect the observed impurity distribution in the ingot. The evaporation of an impurity depends on the growth rate and exposed melt surface area [51.20]. The approximate effect for selected impurities is shown graphically on the right-hand side of Fig. 51.5 for growth in a vacuum. By selecting an appropriate partial vacuum level, the distribution of dopants such as P or Ga can be made nearly uniform along most of the ingot length. The importance of a vacuum for reduction of P content in the material is also evident, although the magnitude of such reduction is small.

In FZ growth, or other semicontinuous growth processes, the impurity distribution, given by Peizulaev's equation [51.21], is more complex, especially if both effective segregation k and effective evaporation g coefficients are incorporated and if more than one growth pass is made on the silicon rod

$$\frac{C_n(x)}{C_0} = \left[\frac{k}{(k+g)} \right]^n \left[1 - (1-k-g)Z_n e^{-(k+g)x} \right],$$

where

$$\begin{aligned} Z_n &= n - \sum_{s=1}^{n-1} (n-s)(k+g)^{s-1} \\ &\times e^{-s(k+g)} \left[\frac{(s+x)^{s-2}}{s!} \right] \\ &\times \{(s-1)x + (s+x)[1 - (k+g)x]\}, \end{aligned}$$

where n is the number of times the ingot is zone-melted, and $C_n(x)$ is the impurity concentration at position x along the ingot (x is in units of melt zone length) after n solidification passes. Here, C_0 is the initial concentration of the impurity in the feed rod (assumed uniform).

Figure 51.6, analogous to Fig. 51.5 for CZ growth, gives the distributions of selected impurities as a function of position along a FZ ingot or other semicontinuously grown silicon form where continuous melt replenishment is used. A total length equivalent to 20 melt zones is depicted.

Note that the characteristic shape of the impurity profiles differs from the CZ case. However, judicious use of a partial vacuum can again allow flatter profiles for impurities that evaporate, and can allow phosphorus removal to some extent.

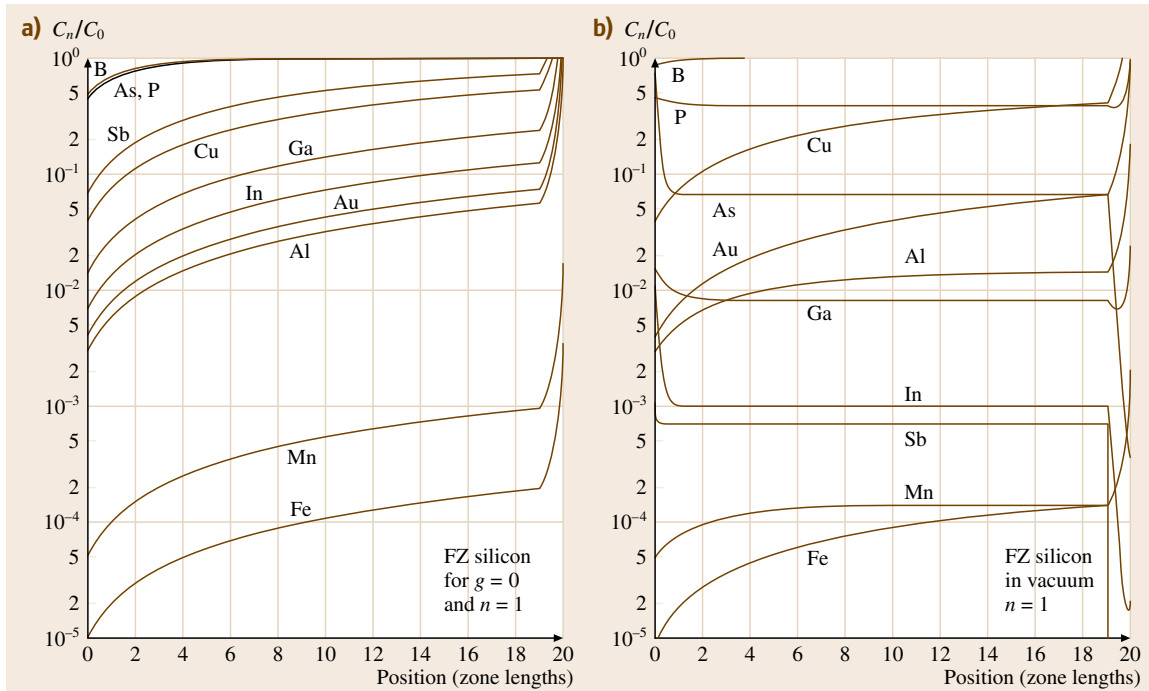

Fig. 51.6a,b Distribution of selected impurities as a function of position along ingot for FZ or other semicontinuous solidification processes with continuous melt replenishment carried out in near-atmospheric pressure (a) and in vacuum (b) (after [51.20])

For CZ growth near atmospheric pressure, the flat-test doping profiles that can be attained are those shown in Fig. 51.5, where all dopant is mixed into the initial melt volume. On the other hand, for FZ growth and other semicontinuous processes, if the dopant has a small segregation coefficient (Ga for example), there is an advantage to inserting the dopant in the first melt zone rather than having it uniformly distributed along the feed rod. This is called pill doping and results in a flat doping profile. Impurities with large segregations coefficients (B, P) must be added continuously with consumption of the feed rod.

Typically, CZ growth is conducted with an argon or argon/partial vacuum ambient and the gas flows down over the seed and melt interface, then over the rim of the crucible and down toward the bottom of the growth furnace. In this way, the copious amounts of SiO_x that form from dissolution of the quartz crucible are swept away from the growth region. FZ growth is typically conducted in a slight overpressure of argon. While growth can be done in a vacuum, some evaporation of silicon will result and cause growth disruption problems if solid Si deposits flake off the chamber or

radiofrequency (RF) coil surfaces and fall into the melt zone.

51.2.3 Multicrystalline Ingot Growth

Using a container to shape the growing ingot instead of manipulation of the solid–liquid–vapor boundary greatly simplifies control of the growth process, allows much larger ingots, and allows ingots to have a square cross-section. All of these factors improve productivity. A schematic diagram of the directional solidification (DS) or casting process is shown in Fig. 51.7. Silicon can be melted in the same container in which it is solidified, eliminating the top vessel in Fig. 51.7, which is designated directional solidification. Alternatively, it can be melted in one container and poured into a second container for solidification, as implied in the figure. This might properly be called casting with directional solidification. However, the terms DS and casting tend to be used interchangeably for either process.

Either induction (shown in the figure) or resistance heating can be used. The heat source, insulation, and heat sink are designed to provide a nearly unidirectional

Fig. 51.7 Schematic diagram of the directional solidification process for multicrystalline silicon (after [51.22])

temperature gradient to drive columnar growth, and some relative motion may be imparted to components as growth progresses. Square-cross-section, flat-bottomed silica crucibles contain the liquid silicon. They are coated with silicon nitride to minimize sticking of the ingot to the crucible, and are a one-use item. Because of the crucible–ingot contact, single-crystal growth is not generally achieved, although some attempts at seeding have been reported, as mentioned earlier.

The same impurity distribution equation applies here as for CZ growth, and the general impurity profiles

follow those in Fig. 51.5 (melt residence time and melt surface area exposed to the ambient modify the details of the profiles in the case of a vacuum ambient). There are additional impurity phenomena to contend with in this process that are not present for CZ growth. Because the melt and the grown ingot are in contact with the container for an extended period of time, impurities can both dissolve and diffuse into the melt and later diffuse into the sides and bottom of the ingot from the crucible. Metallic impurities in the melt are strongly segregated to the last layer to freeze at the top of the ingot. During cool down of the massive ingot, these impurities can diffuse back into the top region of the ingot. These phenomena, along with small grain sizes at the ingot bottom and sides, require that a portion of the bottom, sides, and top of the ingot be cropped away because the minority charge carrier there is too low for adequate PV performance.

In the electromagnetic casting process (EMC) method, container walls comprised of water-cooled, electrically conductive *fingers* provide the sidewall melt confinement during a semicontinuous casting process. Silicon is prevented from making substantial contact with these walls by Biot–Savart law repulsion between the fingers and the melt. This is visualized in Fig. 51.8a, where a helical induction coil, a cylindrical array of fingers, and the Si melt are depicted in a top sectional view. The current directions at one instant in the RF cycle are shown. The induced currents in the fingers and in the melt are in opposite directions, giving rise to the repulsive force. In PV ingot production, a square array of fingers is used and new material is fed into the top of

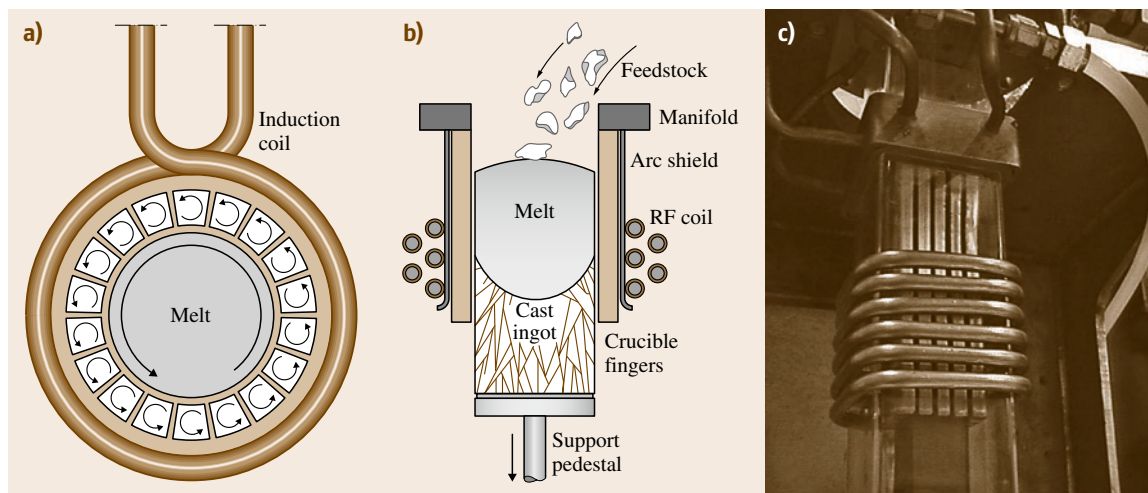

Fig. 51.8 (a) Biot–Savart repulsion [51.23], (b) EMC schematic [51.22], (c) EMC laboratory apparatus

the container while the ingot is continuously withdrawn from the bottom. A schematic of the process is shown in Fig. 51.8b, and a small, laboratory-scale apparatus is shown in Fig. 51.8c.

The impurity distribution profiles in EMC ingots follow the Peizulaev equation, since the configuration is essentially like float zoning, and the curves of Fig. 51.6 apply. Again, the details of the profiles under vacuum will depend on melt residence time and melt surface area exposed to the ambient.

In current production, ingots weighing 1 metric ton are grown with a $35 \times 35 \text{ cm}^2$ cross-section and length of $\approx 4 \text{ m}$, at a throughput (with sawing) of $500 \text{ m}^2/\text{day}$ – approximately seven times faster than any other ingot growth method. The ingots are generally cleaner than DS ingots, but have smaller grain size, with the PV conversion efficiency being about the same.

51.2.4 Silicon Ribbon or Sheet Growth

Many approaches to ribbon or sheet growth of silicon have been made over the years. Only two are in large-scale use at the time of this writing. They are the EFG and string ribbon methods mentioned in the introduction. Other methods that had been pursued until recently are dendritic web growth and a form of horizontal ribbon growth on substrate (RGS) where melt is solidified on a moving substrate that is later detached for reuse. There are indications that RGS growth may reemerge on the PV scene, so this section will summarize the EFG, string ribbon, and RGS techniques.

The EFG technique utilizes a die that is wetted by liquid silicon. The liquid rises up capillary channels in the die to reach the die top, and connects to a seed. As the seed is pulled upward, the top portion of the liquid meniscus continually solidifies, adding growth to the seed. The bottom of the meniscus spreads to the outer edges of the die top and is pinned there. The rising of liquid up the capillary channel is governed by Laplace's equation, which relates the pressure difference Δp across a liquid surface to the two principal radii of curvature of the surface R_1 and R_2 , and the surface tension γ as $\Delta p = \gamma(1/R_1 + 1/R_2) = \rho gh$. The liquid will rise vertically to a height h ; ρ is the liquid density, and g is the acceleration due to gravity. For capillary channels comprised of plates or annular tubes, one radius of curvature R_2 is approximately infinite and the other is $R_1 = s/2 \cos \theta$, where s is the plate or tube separation and θ is the wetting angle, so $h = (2\gamma/\rho gs) \cos \theta$. For silicon in graphite dies, $\theta \sim 0$ and $h \sim 2\gamma/\rho gs$.

Heights of several centimeters to 10 cm could be used, but for a number of practical reasons the height is kept quite small (impurity segregation is improved because back-mixing of the rejected impurities is better, the meniscus is higher and there is less susceptible to freeze-out to the die, the meniscus is more stable, and pick up of SiC particles on the ribbon surface is reduced).

A schematic of EFG growth using an annular die is shown in Fig. 51.9a. EFG wafer growth for PV use is similar, with the tube having eight flat faces. Sections of octagonal tubes with 10 and 12.5 cm faces are shown in Fig. 51.9b. After growth, the tubes are transported to a laser-cutting station, which removes rectangular cell blanks from the tube faces.

Typically, induction heating is used and the tubes grow in an argon ambient at about 2 cm/min linear pulling speed. FZ-type impurity profile equations apply, since the process is continuous with melt replenishment.

Fig. 51.9a,b Schematic of EFG tube growth (a); 10 and 12.5 cm face octagonal tube sections (b) [51.12]

Fig. 51.10a,b Schematic of string ribbon growth (a) and (b) a growing ribbon [51.24]

However, the effective *zone length* is extremely large. Also, the fast pulling speed, lack of rotation, and capillary die restriction of back-mixing of impurities rejected at the solid–liquid interface back into the melt all reduce the effective segregation.

The string ribbon growth process is shown schematically in Fig. 51.10, along with its original ESP implementation using a quartz crucible and graphite filament *strings*. Two thin filaments enter the bottom of the crucible through small openings, pass upward through the melt, and are bridged above the melt by a seed plate. A liquid meniscus rises up to the seed plate and contin-

ually solidifies onto it as the string–seed plate assembly is moved upward at about 2 cm/min.

Carbon-based strings are typically used. They are easily wetted by the liquid silicon, and become an integral, imbedded part of the ribbon, but have the disadvantage of nucleating many small grains near the ribbon edges. The central portion of the ribbon, however, is reasonably large-grained. Other string materials (based, e.g., on alumina or quartz) can be used and nucleate much fewer grains at the edge [51.24], but the contact to the ribbon is less definite and the thermal-expansion mismatch causes them to partially or totally break away from the ribbon edge during cooling. Figure 51.11 shows the development of grain structure for graphite filaments and a graphite *seed* plate, as well as the lack of grain nucleation at the edge when quartz filaments are used. Graphite can be used for the crucible, as well as quartz.

A drawback of both EFG and string ribbon growth is the slow areal throughput. EFG addresses this by effectively growing eight ribbons simultaneously via the eight-sided tube structure. In modern string ribbon production [51.26], a long and narrow graphite mesa crucible is used to retain the continuously replenished melt by capillarity on its top surface. The long edges of the mesa are close and parallel to the ribbons, and the edges define the base of the meniscus from which the ribbons grow. Multiple pairs of strings (four in the present *quad* growth system) are used to delineate the edges of the ribbons. The mesa crucible thus plays a similar role to the die in EFG growth, the main difference being that the melt is replenished directly onto a region of the mesa top and flows laterally along it rather than arriving via distributed capillary channels as in EFG. The small volume of the melt zone reduces heater power requirements and hot-zone material requirements for growth, and the close proximity of the mesa edges to the ribbon helps to stabilize flat ribbon growth.

Impurity and dopant distribution in this system is basically governed by the same equation as for FZ growth, with some ribbon-to-ribbon variations in concentrations due to the path length differences from the replenishment point to each ribbon.

Large-area solid–liquid interface growth with heat removal perpendicular to the pulling direction has the potential to be the highest throughput silicon sheet growth method. A number of variants of the process have been tried in the past, but none are currently in large-scale commercial production. A representative schematic, in this case of the ribbon growth on sub-

Fig. 51.11 (a) Development of grain structure in a 32 mm wide ribbon grown with graphite filaments and *seed* plate [51.25]. **(b)** A 10 mm long portion of the edge of a 20 mm wide ribbon grown with quartz filaments, showing no grain nucleation [51.24]

strate (RGS) process, is shown in Fig. 51.12. Some approaches utilize a moving substrate that is reusable. Others attempt to grow the ribbon off of the free melt surface in a crucible. The important aspect is that the length of the melt zone b be much greater than the sheet thickness t . Then fast pulling speeds can be achieved according to the equation

$$V_s = \frac{4\alpha K_m b}{(2K_m - \alpha t)tL\rho_m} \Delta T,$$

where α is the effective coefficient of heat transfer, ΔT is the temperature gradient between melt and substrate (or free surface, if no substrate is used), L is latent heat of fusion, ρ_m is the density at the melting temperature, and K_m is the thermal conductivity at the melting temperature [51.27]. The equation predicts a 6 m/min growth rate at $\Delta T = 160^\circ\text{C}$, and experimental pulling speeds near that value have been realized (Fig. 51.13). Horizontal growth of this type can be hundreds of times faster than vertical ribbon pulling, particularly if b and ΔT are maximized.

51.2.5 PV Silicon Crystal Growth Approaches

Of the many approaches that have been tried for PV silicon growth, only six are currently in commercial use. The traditional CZ method (and to a lesser extent, the FZ method) produces single-crystal silicon ingots that yield the highest-efficiency silicon solar cells. The DS and EMC multicrystalline ingot methods offer simpler operation and higher throughput (especially EMC) but a somewhat lower cell efficiencies. Ribbon growth eliminates the need for wafering and hence provides better feedstock utilization. The two methods in current use are EFG and string ribbon growth. They provide cell efficiencies similar to that of multicrystalline ingot. The family of horizontal, large solid-liquid interface

Fig. 51.12 Schematic of the RGS sheet growth process (after [51.22])

Fig. 51.13 Wide silicon sheet growing at 3 m/min (AstroPower, 2002)

techniques provides much faster sheet growth, but so far these have not been viable commercially, with cell performance limited by small grain size and high impurity content. Passivation of multiple, small grains has also proved difficult in thin-film silicon growth on substrates, and no commercially viable silicon thin-film growth approaches have been found yet.

51.3 Cell Fabrication Technologies

The main challenge of PV fabrication technologies is developing ways to cost-effectively mass-produce high-performing devices with the highest yield, reliability, and consistency. Capital efficiency, equipment efficiency, cost of production, and device performance have to be optimized to achieve these goals. In this section, in addition to the commercial cell fabrication technologies, a brief review of the advances in the silicon solar cell technologies currently being pursued by

various researchers will be discussed. The basic device structure will be discussed and the commercial production tools and process will be highlighted.

51.3.1 Homojunction Devices

Solar cells manufactured by nine out of the top ten PV cell companies in 2005 were based on homojunction devices. In this structure, only one type of semiconductor

Fig. 51.14 Cross-section of a commercial silicon solar cell (after [51.28])

material, crystalline silicon, is used on both sides of the junction. The device structure is shown in Fig. 51.14.

A p-type crystalline silicon wafer (typically $225\ \mu\text{m}$ thick and $156\ \text{mm} \times 156\ \text{mm}$ in size) is used as the base substrate. After cleaning and/or texturing the front surface, n-type emitter is formed by a diffusion process (junction depth of about $0.3\ \mu\text{m}$). The front and back side are isolated by plasma or chemical etching or laser scribing. An antireflection coating of silicon nitride (about $75\ \text{nm}$ thick and refractive index of about 2.10) is deposited using plasma-enhanced chemical vapor deposition, low-pressure chemical vapor deposition, or sputtering. The front (silver) and rear contacts (aluminum and silver) are screen-printed with metallic inks and subsequently fired to make good mechanical and electrical contact. The front metal coverage is typically 8%. The completed cells are then tested and classified according to the cell parameters. The commercial efficiencies of solar cells based on multi- and monocrystalline silicon are in the range 14.5–15.5 and 16.0–17.0%, respectively. The efficiency ranges are due to the material quality, cell design, and process tools. The efficiency of monocrystalline solar cells is higher as they can be more effectively surface-textured and the electronic quality of the material is better than that of multicrystalline silicon. In the following section, each of the process steps used in commercial cell sequence and the improvement techniques being evaluated will be described [51.29, 30].

Surface Damage Removal and Texturing

In this step, the surface damage resulting from sawing is etched off using hot, concentrated (10–30%) sodium hydroxide (NaOH) solution. Approximately $10\ \mu\text{m}$ of

silicon is removed during the process. About 200 wafers are etched in a batch process. Monocrystalline silicon substrates are subsequently textured using a low-concentration etch containing 2% sodium hydroxide and isopropyl alcohol (IPA). The (100) crystal planes are etched relatively faster than other planes. This results in the intersection of (111) planes and the exposed surface forms with tiny pyramids, about $3\text{--}5\ \mu\text{m}$ in size. This process removes an additional $10\ \mu\text{m}$ of silicon.

For the past 5 years, a new technique, isochemical texturing, has been commercialized for saw-damage removal and texturing for multicrystalline wafers. The process involves use of an acid-based etch solution [hydrofluoric (HF) and nitric acid (HNO_3)] which is a standard etch in semiconductor wafer preparation. The main difference is that the etch solution is kept at a constant temperature, below $10\ ^\circ\text{C}$. Only about $10\ \mu\text{m}$ of silicon is removed, resulting in a substantial saving in raw material. Texturing of multicrystalline silicon wafers increases the conversion efficiency of the cells by reducing reflection and enabling advanced cell design parameters. A special feature of the process is that it can be performed as an inline process, hence enabling the use of thinner silicon substrates.

Emitter Formation

The semiconductor junction is formed by phosphorus diffusion across the entire front surface. The process is carried out in a tube furnace using POCl_3 as the dopant source. Inline belt furnace diffusion (using phosphoric acid solution as the dopant source) is increasingly being used to enable thin wafer processing. The semiconductor junction of the majority of commercial solar cells is about $0.3\text{--}0.5\ \mu\text{m}$ and the surface concentration is about $5 \times 10^{20}\ \text{cm}^{-3}$. The sheet resistivity (a measure of lateral resistance in the n-type doped layer) of the commercial cells is about $50\ \Omega/\text{square}$. The diffusion of dopant from a nearly infinite source into silicon at high temperature $> 860\ ^\circ\text{C}$ results in a complementary error function (erfc) or similar distribution of phosphorus (as shown in Fig. 51.15).

Excess phosphorus beyond the solid solubility limit is precipitated as inactive phosphorus in a silicon region called the *dead layer*. In this region the minority-carrier lifetime is significantly reduced or the generated carriers are recombined instantly. The high surface concentration of phosphorus and low sheet resistivity are not optimum conditions for maximizing the generation of carriers. However, widespread use of this approach is due to its compatibility with high-volume manufacturing tools such as screen-printing metallization practiced

Fig. 51.15 Diffusion profile of the silicon surface (after [51.31]) (SIMS – secondary ion mass spectroscopy)

in the surface-mount assembly industry. There are several approaches being actively investigated to enhance the performance of solar cells by reducing the dead layer and developing screen-printing paste compatible with higher sheet resistivity and lower surface concentration of phosphorus [51.31].

Junction Isolation

During the diffusion step, the edge and the rear of the wafers also gets diffused. Hence, to prevent leakage paths, the front and the rear need to be isolated. There are several techniques used to achieve this in commercial solar cell manufacturing. One of the widely used techniques is a plasma etch by which the edges of coin-stacked wafers are etched. However, due to the textured surface of the wafer, some active area of the cell in the front surface is also etched. Another technique involves the use of a laser system, where the edges of the wafers (front or rear) are trenced or cleaved. During the past 3 years, a new technique has been commercialized, enabling thin wafer processing. This technique is based on chemically etching off the rear phosphorus junction without etching the front [51.33].

Phosphorus Glass Removal

In this step, the phosphorus glass formed during the diffusion step is removed using a dilute hydrofluoric acid etch. The glass is very thick (20–40 nm) and would affect the effectiveness of the antireflection layer that will

be deposited later in the process. This step can be done as a batch or inline process.

Antireflection Coating Deposition

The goal of this step is to minimize the reflection of incident light, thereby increasing PV efficiency. The weighted average of reflected sunlight from a bare silicon surface is about 30%. Under glass in the encapsulated stage, this value can be reduced to about 15%. By texturing the surface the reflection can be reduced to 10%. In order to further decrease the reflectance, an antireflection (AR) coating is applied to solar cells. By selecting an appropriate film thickness and refractive index (RI) of the AR coating, the reflection can be reduced to below 4%. Apart from ability to reduce reflection, the AR coating must be transparent, i.e., it should not absorb incident sunlight.

The most widely used antireflection coating is a silicon nitride film (about 75 nm thick with RI of about 2.10), deposited by plasma-enhanced chemical vapor deposition (PECVD). In addition to providing the antireflection properties, the silicon nitride deposition process introduces hydrogen which diffuses into bulk silicon. This hydrogenation improves the electronic quality of surface and bulk silicon by means of passivation [51.34].

Metallization and Contact Sintering

In this step, both top and rear contacts are printed and sintered. A typical front pattern is shown in Fig. 51.16.

The most widely used technique to deposit metal paste is screen printing. The top contact is a paste containing silver with organic and glass binders. On the

Fig. 51.16 Front contact metallization of a solar cell with antireflection coating [51.32]

rear, an aluminum paste is printed in all areas except where silver paste is applied to make contacts for the external circuit. The aluminum paste after sintering provides a p^+ surface (back surface field) and additional gettering of impurities in the bulk silicon. The pastes are applied sequentially with a drying step between each printing step. The printed wafers are then fired to make contact with the silicon. The front paste fires through the silicon nitride layer and makes contact to the n-type layer. If the sintering step is very aggressive (higher temperature, longer duration), the metal will make contact to the p-type bulk silicon, resulting in electrical shorting. On the other hand, if the paste is not sintered adequately the strength of the bond to the interconnection between two solar cells will be weak and will not have the required chemical and mechanical contact properties. Hence the selection of the paste, printing height, and the firing conditions are very important in determining the performance of the cell. This step determines many of the cell parameters and long-term performance of the solar cell. The strength of the interconnection between the contacts and the tabbing ribbon is affected by the paste/sintering characteristics and the soldering process [51.35].

Testing and Binning

In this last step, the solar cell is measured using a sun simulator at standard testing conditions (STC), i.e., irradiance of 1000 W/m^2 with an air mass 1.5 spectrum (AM 1.5) at 25°C . STC is selected as it is easy to reproduce in the laboratory. The cell is tested against a calibrated cell. Cell performance in air will be different from its performance under encapsulated conditions due to the difference in optical coupling and the increased series resistance. The cells are sorted and binned according to their electrical performance and various mechanical and visual defects such as cosmetics, color nonuniformity, edge chips etc. The finished cells are packed for further processing into modules. The modules will operate at conditions other than STC, hence the module manufacturer provides temperature coefficients of voltage and current as well as predicted performance as a function of irradiance.

51.3.2 Enhancing Solar Cell Performance

The gap between the efficiency of laboratory cells and commercial cells is decreasing with the commercialization of several high-efficiency techniques. Efficient solar cell design involves maximization of carrier generation and carrier collection. The generation of carriers

in a silicon solar cell depends on the electronic quality of substrates (minority-carrier lifetime), the active area (the area not covered by metal contact lines), spectral response, absence of dead layer, etc. The collection of carriers depends on bulk and surface passivation and the lateral and contact resistance.

The performance of conventional commercial cells is limited by the requirement of the metal pastes, the capability of the printing equipment, and surface recombination of the generated carriers. The front metal paste requires heavier phosphorus diffusion and increased surface concentration of phosphorus. This requirement affects current generation and current collection. The use of fine line-printing techniques, better screens, and better metal pastes reduces the shading losses due to metal coverage. The development of new pastes compatible with lower surface concentration of phosphorus and higher sheet resistivity will increase the current generation capability. The incorporation of a surface passivation layer will enhance the beneficial effects of cells with higher emitter sheet resistivity and thin cells. In addition, thin cells (less than $150 \mu\text{m}$) require a back surface field which does not bow the cells. All of these topics are being actively pursued by several paste manufacturers in collaboration with cell technologists.

51.3.3 Advanced Commercial Solar Cell Concepts

In this section, a few of the commercial sequences which are not based on conventional screen-printing technology are presented. These sequences are applicable to limited types of substrates. However, several research institutions and PV companies are trying to incorporate some of the concepts of these cells into conventional screen-printing sequences.

Buried-Contact Cells

The buried-contact solar cell sequence is one approach which has been commercialized to overcome the limitation of screen printing. Cell efficiencies up to 18% (laboratory efficiency 22.7% record cell) have been demonstrated on monocrystalline (CZ) wafers [51.36]. In this sequence the grooves are formed on the top surface into which metal contacts are plated (Fig. 51.17).

Additional high-efficiency concepts incorporated in this sequence are surface passivation and a shallow emitter with deep diffusion under the contacts. In addition to an increased number of steps, the sequence involves several high-temperature steps. Hence it re-

Fig. 51.17 Cross-section of a buried-contact solar cell (after [51.28])

quires monocrystalline silicon wafers with low oxygen content. This limits the widespread commercialization of buried-contact solar cells.

Back-Contact Cells

A back-contact (interdigitated contact) cell sequence has been commercialized for high-lifetime n-type wafers. Cell efficiencies up to 22.2% have been demonstrated in large-scale production [51.38]. The sequence includes a textured front surface with antireflection coating, well-passivated surfaces, and screen-printed metal contacts on the rear. The special feature of the cell (shown in Fig. 51.18) is that all the contacts are on the rear, thereby reducing the shading losses and improving the cosmetic appearance of the cells.

HIT Cells

The heterojunction with intrinsic thin layer (HIT) cell sequence has been commercialized. Efficiencies of HIT cells up to 21.8% have been reported on n-type substrates (as shown in Fig. 51.19). The unique feature of

Fig. 51.18 Back-contact solar cell [51.37]

Fig. 51.19 HIT cell structure [51.37]

this sequence is the incorporation of a thin amorphous silicon layer on both surfaces of the solar cell [51.39]. These layers provide high-quality surface passivation to achieve a very low surface recombination velocity. An additional advantage of this design is that the cell can be bifacial, thereby converting backscattered light into useful power output. TCO in Fig. 51.19 refers to a thin-film conducting oxide.

It is exciting that many of these advanced cell concepts, once only achievable in laboratory-scale devices, are now being used successfully in manufacturing.

51.4 Summary and Discussion

The silicon photovoltaic industry has been on a rapid growth path over the past decade – on the order of 30–40% per year. As of 2007, the consumption of high-purity silicon for solar cells has exceeded the amount used for all other electronic applications. The rapid growth has presented challenges in all segments of the PV value chain (Fig. 51.2). However, as these challenges are met and the industry benefits from economies of scale, the technology becomes ever stronger and

closer to meeting the cost and performance milestones that will establish it as a viable source of a significant portion of world energy needs.

The well-established technology base and ready availability, proven performance, and salubrity of silicon, coupled with economies of scale in larger factories, will likely allow Si to remain the dominant PV material for the foreseeable future. The rapidly increasing demand for polycrystalline silicon feedstock for PV

use has caused a disruption in the demand/supply ratio, but this is not a fundamental problem, nor does it represent a fundamental shortage. It is, rather, a planning/forecasting issue which was exacerbated by: (1) investor caution resulting from the economic and high-technology downturn around the year 2000, and (2) investor skepticism of the viability and continued growth projections of silicon photovoltaic technology. Part of this investor reluctance results from uncertainties about whether there will be a future role of compound semiconductor thin films in photovoltaics. The performance and costs of the thin-film approaches have not so far been competitive with silicon. Furthermore, the Earth's crust contains 27.7% Si, in contrast to 0.00002% Cd, 0.00001% In, 0.000009% Se, and 0.0000002% Te (commonly used thin-film elements). So it is difficult to see how improved costs for thin-film PV can come to fruition despite the fact that they use a thinner layer of semiconductor material. The temporary shortage of polycrystalline feedstock has instigated numerous metallurgical approaches to the purification of silicon, in the hope that adequate purity for solar cells can be achieved at a lower cost than that of the Siemens process. However, this is a difficult challenge because 99.9999% or six-9s pure silicon is required for PV.

In single-crystal CZ ingot growth, we are likely to see increased effort to make hot zones more energy efficient, to grow larger diameters, and to achieve continuously melt-replenished long growth runs. There will be continuing effort to achieve more wafers per length of ingot, and to take advantage of potentially higher cell efficiencies afforded by thinner wafers when back surface fields are used in the cell design. Despite the potential advantages of FZ material, it is unlikely that its role in PV will increase significantly because of higher costs for the crack-free, long cylindrical feedstock it requires and the difficulty in producing the larger FZ diameters. Multicrystalline casting, directional solid-

ification, and electromagnetic casting command the largest share of the Si PV market. This trend is likely to continue because the processes and equipment are simpler and the throughputs are higher (especially for electromagnetic casting) by a factor of 5–20.

Even though ribbon and sheet growth technologies have the advantage of minimal silicon consumption and elimination of wafering, it is difficult for them to compete effectively with the higher throughput of ingot technologies. Their challenge will be to increase areal throughput via wider ribbons, multiple ribbons or other approaches. The effective areal throughputs of ingot growth range between 30 m²/day and 600 m²/day per machine. By contrast, a capillary die octagon tube growth machine produces about 20 m²/day and string-supported ribbon machines produce about 8–9 m²/day. We will probably see continued progress in horizontally pulled, large-area solid-liquid interface sheets by some variant of the horizontal growth method because the throughput potential is enormous and one growth furnace could easily generate material for 35 MW/a or more of solar cell production.

The future is expected to bring continued exploration of thin-layer Si growth approaches, in search of ones that have significant economic advantages over the best ingot and sheet techniques. Successful ones will have fast deposition rates, large grain sizes, high efficiencies (at least 14% production efficiency), compatibility with low-cost substrates, and amenability to low-cost cell fabrication schemes. It is not likely that production of thin-layer Si PV modules will account for a significant fraction of the mainstream PV market for at least 10 years, although they, like the ingot and sheet approaches, would have substantial advantages over many other thin-film PV approaches. These include the simple chemistry, the relative abundance of the Si starting material, compatibility with SiO₂ surface passivation, and relative lack of toxicity.

52. Wafer Manufacturing and Slicing Using Wiresaw

Imin Kao, Chunhui Chung, Roosevelt Moreno Rodriguez

Wafer manufacturing (or wafer production) refers to a series of modern manufacturing processes of producing single-crystalline or poly-crystalline wafers from crystal ingot (or boules) of different sizes and materials. The majority of wafers are single-crystalline silicon wafers used in microelectronics fabrication although there is increasing importance in slicing poly-crystalline photovoltaic (PV) silicon wafers as well as wafers of different materials such as aluminum oxide, lithium niobate, quartz, sapphire, III–V and II–VI compounds, and others. Slicing is the first major post crystal growth manufacturing process toward wafer production. The modern wiresaw has emerged as the technology for slicing various types of wafers, especially for large silicon wafers, gradually replacing the ID saw which has been the technology for wafer slicing in the last 30 years of the 20th century. Modern slurry wiresaw has been deployed to slice wafers from small to large diameters with varying wafer thickness characterized by minimum kerf loss and high surface quality. The needs for slicing large crystal ingots (300 mm in diameter or larger) effectively with minimum kerf losses and high surface quality have made it indispensable to employ the modern slurry wiresaw as the preferred tool for slicing. In this chapter, advances in technology and research on the modern slurry wiresaw manufacturing machines and technology are reviewed. Fundamental research in modeling and control of modern wiresaw manufacturing process are required in order to understand the cutting mechanism and to make it relevant for improving industrial processes. To this end, investigation and research have been conducted for the modeling,

characterization, metrology, and control of the modern wiresaw manufacturing processes to meet the stringent precision requirements of the semiconductor industry. Research results in mathematical modeling, numerical simulation, experiments, and composition of slurry versus wafer quality are presented. Summary and further reading are also provided.

Wafer manufacturing (or *wafer production*) refers to a modern process of producing single- or polycrystalline wafers from crystal ingots (or *boules*) of different

sizes and materials. The majority of wafers are single-crystalline silicon wafers used in microelectronics fabrication. Due to the increasing importance of the pho-

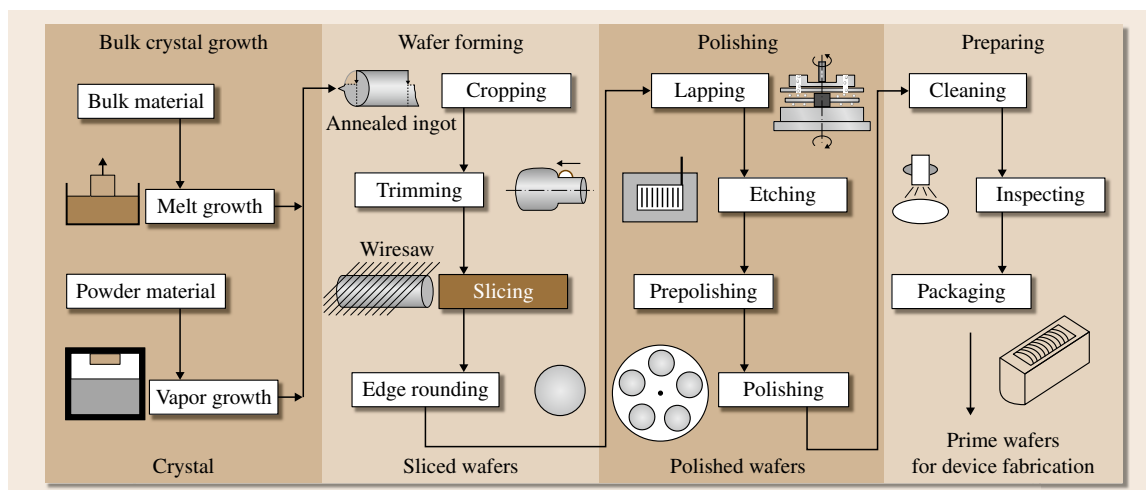

Fig. 52.1 Wafer manufacturing: from crystal ingots to prime wafers. Four categories of manufacturing operations are illustrated: bulk crystal growth, wafer forming from crystalline ingot, wafer polishing to produce prime wafers, and wafer preparing. Each category includes several operations

to voltaic (PV) industry, polycrystalline silicon wafers (although some PV wafers are single-crystalline silicon) are being produced in increased volumes. Wafers of different materials such as aluminum oxide, lithium niobate, quartz, and others have also been produced.

The health of the wafer manufacturing industry has become a good economic indicator in this microelectronics and information age; for example, when the economy suffered a downturn in the USA around 2001, the wafer production industry also suffered a drop in production due to lower demands. On the other hand, when the economy was picking up a few years afterwards, demand for wafer production heralded this recovery before it happened. With greater reliance on microelectronics, computers, and information worldwide in the 21st century, this trend is expected to become stronger than ever.

Wafer manufacturing includes a series of processes, beginning with crystal growth and ending with prime wafers, as illustrated in Fig. 52.1, in which a process flow of wafer manufacturing with various categories of operations is shown [52.1]. Slicing is the first major postgrowth wafer-forming process, and is primarily accomplished using various technologies, discussed in Sect. 52.2. The first modern wiresaws were designed and built by HCT. The first generation of industrial wiresaws were employed to slice polysilicon photovoltaic (PV) wafers. Since the introduction of the technology of the slurry wiresaw in the early 1990s, this approach has seen a dramatic increase in usage

in the USA and worldwide, replacing thousands of inner-diameter (ID) saws, primarily for the following reasons:

- Acceptance of slurry wiresaws for the slicing of silicon wafers, especially for single-crystalline silicon wafers in the microelectronics industry at the turn of the century.
- In contrast to ID sawing, wiresaw slicing results in higher throughput and can slice large wafers of different crystal materials.
- Recent research advances in slurry wiresaw and slicing manufacturing processes [52.1–78] have made significant contributions to the understanding of fundamental manufacturing process modeling, promoted research and development (R&D), and provided insights into parameter optimization and process control.
- The versatility of wiresaws to slice wafers of various sizes made of different materials.

When the single-crystalline silicon wafer manufacturing industry finally adopted the wiresaw as the main slicing tool towards the end of the 1990s, it prompted a wholesale replacement of thousands of inner diameter (ID) saws which had been the only slicing tool for decades until then. Many wiresaw equipment producers also appeared on the horizon, as well as ancillary industries for the supply of consumables such as saw wire, abrasive grits, carrier fluid,

etc. In addition to the silicon industry, wiresaws have also been employed to slice crystal wafers such as LiNbO_3 , SiC , InP , quartz, sapphire, aluminum oxide, and others.

As slurry wiresaw technology continues to become more mature and widely employed, applications in other areas also arise. A case in point is the development in the application of wiresaw reported in July 2005 [52.59]: a special-purpose wiresaw designed by HCT for Corning Inc., which weighs 50 t with a height

of 8 m (much bigger than regular industrial wiresaws), used for slicing fused silica for the production of liquid-crystal display (LCD) image mask blanks, used in the process by which makers of liquid-crystal displays imprint a pattern of electrical circuits onto the *mother glass* for computer and television displays. This example illustrates the potential of modern wiresaws in a variety of applications in the future due to the unique capability, configuration, and nature of the manufacturing process.

52.1 From Crystal Ingots to Prime Wafers

Modern *wafer manufacturing* (also called *wafer production*) includes a plethora of manufacturing operations by which prime wafers are produced from crystal ingots [52.1, 79]. For example, semiconductor devices are built on high-quality substrates and economics demands thin wafers (500–900 μm thick) of large area. Quality requirements of prime wafers include a high degree of crystalline perfection, low defect, low microstructure and subsurface damage, global surface planarization, uniform thickness, and very low residual stresses. Only when these demands are met can the full potential of the various semiconductors be realized. Figure 52.1 illustrates a flow of various processes and categories associated with the production of prime wafers from crystalline ingots.

The technology to produce semiconductor wafers is driven by many factors. New materials result in new applications that, in turn, inspire the design and engineering of new and higher-quality materials, new processing technologies, and special equipment. Broader applications of these wafers and economics demand continuous reduction in costs, improvements in quality, and innovations in materials and manufacturing technology. For example, both the size and quality of silicon substrates have been constantly increasing, and 400 mm-diameter wafer has already been used, although 300 mm wafers are the most well established today. The 400 mm silicon wafer has gradually become the standard in today's microfabrication industry, and will eventually replace 300 mm fab lines. In a similar way, the reduction in silicon wafer costs can spur exponential growth in the consumer market of solar cells.

In the following subsections, the process and operations of wafer production will be discussed.

52.1.1 Semiconductor Single-Crystalline Wafers

Typical semiconductor materials, such as silicon, lithium niobate, III–V compounds, II–VI compounds, and others, are hard and brittle. Silicon constitutes more than 90% of the total consumption of semiconductor materials, and has been extensively used in electronic and photovoltaic (PV) industries. The wafer manufacturing processes from ingot to prime wafers are illustrated in Fig. 52.1. As shown in the figure, slicing is the first major postgrowth process in wafer manufacturing. Recently, wiresaw slicing has emerged as a leading technology of wafer preparation in the semiconductor industry, especially for PV and large silicon wafers due to its capability of cutting ingots of large diameter (e.g., 300 mm and up) with small kerf loss and high yield. Nevertheless, the trend of using large wafers (with diameter of 300 mm or higher) as the future standard in microelectronic fabrication, projected by National Technology Roadmap for Semiconductors (NTRS), Semiconductor Industry Association (SIA), and Semiconductor Manufacturing Technology consortium (SEMATECH) [52.80–83], has virtually eliminated the conventional ID saw as a slicing tool, making the wiresaw an indispensable tool for wafer forming.

The importance of manufacture of silicon in the USA is illustrated by the statistics showing that in 1993 the US\$ 3 billion silicon resulted in an average of US\$ 6.67 billion device market per month and a total of US\$ 700 billion electronic equipment [52.80]. This figure has increased to sales of US\$ 10.97 billion device in 1998 [52.82] – a 65% increase over 6 years. Apart from the increase in quantity, quality requirements have also increased. Growing demand in chip surface area

produced annually is expected with the expansion of microelectronics, telecommunication, microelectromechanical systems (MEMS), and medical applications. Accompanied by the increase in wafer diameter, there is an increasing degree of integration of components and a decreasing structural width.

The objective of wafer manufacturing (or *wafer production*) for semiconductor industry is to produce prime wafers ready for microelectronics or PV solar cell fabrication, from single- and polycrystalline ingots. Four categories are outlined in Fig. 52.1 and described in the following. For the fabrication of PV solar cells, wafers are often processed as-sliced, without going through the rigorous process in Fig. 52.1, which is typically used for the production of microelectronic-scale silicon prime wafers.

Crystal Growth

Silicon ingots are grown using various techniques of crystal growth as presented in the earlier chapters of this Handbook, including bulk melt growth, powder vapor growth, and others, as illustrated in Fig. 52.1. A casting process is often employed for polysilicon ingots, normally in square shape, for PV wafers. Typical single-crystalline silicon ingots assume a cylindrical shape when grown, up to many feet tall, depending on the process.

Once the crystal ingot is grown it is processed to form wafers and substrates. The processes can be broken into three main categories, as described in the following.

Wafer Forming

The second group of manufacturing operations, also called *wafer forming* as shown in Fig. 52.1, forms the shape of thin wafers. It includes the following operations:

- Cropping both ends of the ingot (especially the tail end, which tends to have higher impurity)
- Trimming it to have a cylindrical shape with consistent cross-sectional area, followed by grinding of the orientation flat or notch to identify the crystalline orientation
- Slicing the ingot into slices of wafers
- Edge-rounding to smooth and remove tiny fractures which may have been formed along the edges of the wafer during the forming operations

Wafer Polishing

The objectives of this group of manufacturing operations are (1) to remove surface waviness and subsur-

face damage from the forming operations, and (2) to polish wafers to high precision (submicron surface roughness) with a mirror surface finish. It includes a series of operations as follows:

- *Lapping*: This is typically the first post-slicing process, based on the mechanical free abrasive machining (FAM) process to remove the surface waviness after slicing. This involves abrasives suspended in slurry to perform the mechanical process of removing the surface roughness and subsurface damage. An initial global planarization is achieved after this process.
- *Grinding*: As the size of silicon wafers becomes larger (300 mm or larger), and slicing is performed by slurry wiresaws, there are increasing demands on the grinding of the surface after slicing operations. One of the main reasons for the employment of the grinding operation is the removal of the surface waviness produced by the slicing process. Grinding using diamond tools is a faster operation than lapping. Often the demands of double-sided wafers also require grinding to be performed with consideration of elimination of the elastic spring-back effect that has commonly been found in lapping of large wafers. The ground wafers can be subject to subsequent lapping and polishing processes.
- *Polishing*: This is the final process in this category, to render well-polished wafers ready for photolithography and microelectronics fabrication to produce microelectronic chips. The standard process at this stage is chemical–mechanical polishing (CMP). Wafers at this stage are called prime wafers.

Wafer Preparing

The category of *wafer preparing* refers to steps through which the prime wafers are cleaned, inspected for defects to assure quality, and packaged in a boat ready to be shipped.

52.1.2 Alternative Wafer Production Processes

While the wafer manufacturing process outlined in Fig. 52.1 represents the general operations in wafer production, different operations in this production process may be skipped, simplified or augmented, depending on the substrate type and the requirements on surface finish. For example, the generic process can be slightly altered with epitaxial growth of a thin

Fig. 52.2 Sliced wafers with epitaxial growth of thin layer of silicon for device fabrication. The sliced wafer is subject to surface grinding using a diamond grinding wheel, followed by the epitaxial growth process to render a finished wafer for device fabrication

layer (5–60 μm) of silicon. By so doing, the etching and CMP process can be bypassed to yield a finished wafer directly. An illustration of such a process is shown in Fig. 52.2. Certain logic gates and devices have been fabricated using these types of epitaxial wafers.

Another example is the processing of photovoltaic (PV) wafer. PV wafers are often employed as-sliced without further polishing after slicing.

52.1.3 Substrate Manufacturing with a System-Oriented Approach

The key processes and challenges in wafer manufacturing are summarized in Fig. 52.3, which shows the flow of operations discussed above. The values after each box represent typical surface roughness. Various issues related to each category of manufacturing operations are summarized in the figure for the manufacturing operations ranging from slicing, lapping, and polishing to inspecting, cleaning, and packaging.

Wafer Forming and Polishing Challenges

Tables 52.1 to 52.5 outline various important issues for consideration at every stage of the wafer production. In Table 52.1, the applications and corresponding issues in wafer forming and slicing are identified, along with research methodology. Table 52.2 outlines different applications in grinding, lapping, and polishing and relevant issues with some possible research approaches, including also considerations of materials and process control.

Wafer Preparing Challenges

Current cleaning, inspection, and metrology techniques used by industry were developed 10–20 years ago. Many recent innovations in metrology and laser-based methodology can satisfy modern demands and be

Table 52.1 Wafer forming: potential applications and issues of consideration, as well as research approaches and methodology. Some items represent future considerations

Potential applications	Issues	Research methodology
Large-diameter substrate	Residual stress, warpage, TTV , kerf loss, dynamics, vibration	Solid and fracture mechanics modeling, stiffness control, stress relaxation, finite element method (FEM), subsurface damage
Apply cutting Si to other crystals	Different properties, process	Model-driven design, flexible manufacturing, optimized automation
Moderate number of slices (10–50): no current technology, cost-effective	Flexibility and versatility on number of slices	Model-based versatile design and fabrication in research and development
Cost reduction	Consumable, kerf loss, materials loss during forming process	Interconnected growth process control for more uniform crystal to reduce crop/trim loss; reduce kerf loss
Brittle, ductile, and very hard materials	Abrasive, wire speed, surface quality	Material- and size-independent substrate manufacturing strategies and equipment

Table 52.2 Applications and issues of consideration for lapping, grinding, and polishing in the wafer production process

Potential applications	Issues	Research methodology
Large-diameter substrate	Residual stress, warpage, TTV , kerf loss, dynamics, vibration	Modeling of stress influence, chemical versus mechanical reactions, requirements (0.35–0.13 μm), high level
Prime wafers of large diameter/size	Global planarization, parallelism of surfaces of wafers, quick removal of initial surface waviness and roughness	Geometry analysis, elastic analysis in grinding, double-sided grinding
Different materials, e.g., ultrahard materials	Abrasive, lapping speed, micro-cracks, defects, contaminants	Control strategies, holder design, expert system, experimental validation
Alternative processes for polishing, e.g., epitaxial growth	Process control, surface finish, orientation tolerance, flatness tolerance	Model-driven design, Taguchi methods, statistical process control (SPC), total quality management (TQM)

Table 52.3 Wafer preparation: the identification of potential applications as well as issues at hand with research approaches

Potential applications	Issues	Research methodology
Nonintrusive, online, multistaged, full-field, whole-wafer inspection	Warp, bow, TTV , size, methods, resolution of measurements	Capacitive probes, moiré, interferometry, and optical metrology
Next-generation cleaning tools	Clean, contaminants removal	Laser-assisted method, gas cluster ion-beam processor, superheated gas chamber

applied in the preparation of substrates. Table 52.3 outlines some issues identified and related research approaches.

Metrology, Inspection, and Quality Control
Technology’s simultaneous move towards smaller devices and larger wafer size has created new challenges

Table 52.4 Wafer manufacturing with a system-oriented approach: integrated issues with suggested research approaches and methodologies

System-oriented manufacturing	Important issues in the future	Research approaches and methodology
Real-time sensing and control of wiresaw manufacturing	Kerf loss, wire thinning and breakage, control, quality assurance	Modeling, dynamics, vibration, thermal and residual stresses, and high-level control strategies. Sensor fusion and metrology systems. Short-pulsed high-intensity laser-assisted cleaning
Integrated computer-based control systems and manufacturing automation	Interconnected processes with surface resolution from 0.5 to 0.18 μm slicing, lapping, CMP, cleaning, metrology, quality, SPC, TQM, reduce cost	Integrated engineering system. Size and material index. Substrate manufacturing systems. Implementation of optimized automation strategy manufacturing management, and expert system. Advanced control strategies, artificial neural network (ANN)
Experimental validation and benchmarking	Lab testing and new industrial equipment development. Yields and cost reduction	Taguchi experimental design. Interconnected methodology from modeling, simulation, to experiments
Industrial technology development in partnership with academics	Leadership and core competence	Industrial manufacturing leadership and knowledge base. Dissemination of research results and information database

for metrology, as desired levels of accuracy cannot be achieved by simply extending current technologies. A suite of new metrological techniques is thus required. Currently metrology is employed mostly in an offline fashion. To reach the technological goals set by NTRS, the role of metrology has to be redirected from offline sampling to inline and in situ control [52.4, 9, 12, 17, 53, 84]. The future research effort in metrology should emphasize inline or in situ measurement for quick process feedback and quality control. Table 52.4 presents system-oriented wafer manufacturing and identifies important issues of research for the future,

along with possible methodology for solutions. Table 52.5 shows the identified metrology issues in wafer manufacturing and suggests several plausible research methodologies. The specific topics can include, but are not limited to, nonintrusive, inline, full-field wafer inspection; optical methods such as Moiré, Fizeau, and Twyman–Green interferometry can provide nonintrusive, inline, full-field measurement of flatness, bow, warpage, and total thickness variation (TTV). Using these techniques, measurement throughput will be significantly increased over current technologies, which translates into cost savings. Also, measurement accu-

Table 52.5 Identified metrology issues in wafer manufacturing and plausible research methodology

Metrology issues	Research methodology
Nonintrusive, inline, full-field flatness, bow, warpage, and TTV measurement	Shadow Moiré, reflective Moiré, Fizeau and Twyman–Green interferometry
Inline residual stress measurement	Moiré interferometry and others
Real-time wire separation inspection	Moiré interferometry and others
Real-time wire thinning inspection	Laser diffraction
Inline metal impurities and contamination inspection	Fiber-optic sensors based on photoluminescence, Raman scattering, photon correlation spectroscopy, and evanescent-wavefield technique

racy, repeatability, and reproducibility can be improved by eliminating scanning by performing measurements on an entire piece simultaneously. In addition, laser speckle technology and fiber-optic sensors can also provide inline and rapid measurement of surface roughness after slicing and lapping, which is important for process feedback and control.

Real-Time Inspection of Wiresaw Operations

Practitioners in the industry of wafer production using wiresawing to slice ingots are often faced with challenges of understanding and optimizing process parameters to improve accuracy and efficiency. From the process monitoring and control point of view, two issues have been identified as having a critical impact on the quality of sliced wafers: uneven separation of wires, and wire thinning during operation. To this end, moiré interferometry and laser diffraction methods, to name but two, can be used to measure these two parameters, which can be fed back to correct the wiresaw operation in real time [52.27, 39, 85].

Inline Residual Stress Measurement

During both crystal growth and wafer production, residual stresses are created that result in warpage (i. e., the

potato chip effect) of the wafer slice. These stresses can be quantified by using the moiré method to measure the wafer warpage before and after the wafer annealing step that relieves the residual stress. This information can then be used to adjust, optimize, and improve the previous steps.

Inline Metal Impurities and Contamination Inspection

Integrated fiber-optic sensors can be designed to remotely sense metal impurities and contamination on the wafers. Material composition can be determined from the spectral response based on photoluminescence. The concentration of various species in a mix can be measured through Raman scattering, while the size of submicron particle contaminants (3–3000 nm) can be measured using photon correlation spectroscopy. A concentration of heavy metal ions as low as 1 ppb in processing baths can be estimated through absorption measurements using evanescent-wavefield sensors. Fiber-optic-based sensors can provide both characterization and feedback during various stages of high-quality wafer producing. Early detection and removal of contaminants will increase yield and reduce downtime.

52.2 Slicing: The First Postgrowth Process in Wafer Manufacturing

Slicing is the first postgrowth process in wafer manufacturing for wafer forming from a crystalline ingot. Different slicing technologies and equipment are discussed in the following.

52.2.1 ID Saws

In the early days of wafer production, inner diameter (ID) saws were employed. An ID saw utilizes the edge of its inner hole to slice through an ingot, as shown schematically in Fig. 52.4. As shown in Fig. 52.4, a thin annular steel blade with a round hole in the middle is coated along the ID edge with industrial diamond abrasive grits, and is stretched with very high tension to

keep the blade surface taut. The ingot to be sliced is fed through the inner-diameter hole, held by the jig shown in the figure. As the ID blade traverses down, a slice of wafer is obtained when the blade slices through the

Fig. 52.4 Schematic of inner diameter (ID) saw for wafer slicing. The ingot, held by the jig, is fed through the inner opening of the ID saw with the inner edge coated by diamond abrasive grits. The annular steel blade is stretched with very high tension and rotates at high speed to slice through the ingot, as shown, by way of a fixed abrasive ploughing machining process ►

ingot. Industrial motion control is employed for the operation and control to generate each slice of wafer.

As the diameter of the wafers in microelectronics application becomes larger, the inner diameter of the hole needs to be enlarged in order to accommodate the ingot and the jig. ID saws are practical for wafers up to 8 inches in diameter. For ingots of larger diameters, vibration becomes excessive, along with limitations of other practical issues, making ID saws unsuitable for wafer slicing.

52.2.2 The Modern Wiresaw

The modern slurry-based wiresaw has emerged as the slicing technology for semiconductor wafer production industry, as well as the preferred tool for slicing of ingots made of various materials. Since a century ago, wire has been utilized as a cutting tool to slice through stones and other materials. However, the literature on slicing using wiresaw in patent disclosures (for example [52.55, 57, 58, 62, 64, 71, 72, 86–89]) and research has only appeared in the last decade. Employed to slice single- and polycrystalline ingots to produce very thin (as thin as 200 μm) and thick wafers, the modern wiresaw is subjected to more stringent requirements to produce wafers with low total thickness variation (TTV), low warp, and low residual stresses.

A schematic of the modern wiresaw is illustrated in Fig. 52.5. A single steel wire is drawn from a supply spool and wound over three or four grooved cylindrical wire guides (four wire guides are illustrated in Fig. 52.5), to form the *wire web* surface on which the crystal ingot mounted on a holding jig is fed, with abrasive slurry manifolds feeding slurry with abrasive grits. As the wire moves with high speed, the ingot on the web is fed downward for slicing. Several hundred slices of wafers are produced simultaneously when the ingot traverses through the wire web to finish the slicing operation. More details of this modern wiresaw will be introduced in Sect. 52.3.

The modern wiresaw has sophisticated control of various parameters for successful precision operation, including control of wire tension [typical industrial proportional–integral–differential (PID) control], slurry temperature, wire speed, duty cycle of wire feed, ingot feed rate onto the wire web, and others. This is done through a computer-based monitoring and control unit to give operators greater flexibility and the ability to control and optimize the process parameters.

In addition, the wiresaw is capable of cutting much harder materials such as some III–V compounds and

Fig. 52.5 Schematic of a modern wiresaw for wafer slicing. The schematic shows a wire supply spool with a single wire, winding over four grooved wire guides, collected by the take-up spool. The winding procedure provides wire webs as a surface of equally spaced wire segments onto which the ingot is fed to be sliced into wafers. Manifolds on both sides of the ingot pour abrasive slurry continuously onto the wire web surface

ceramics with proper abrasive grits and carrier. It has also been shown to work well for highly anisotropic materials such as lithium niobate.

52.2.3 Saws with Diamond-Impregnated Wires

Saws with diamond-impregnated wires are designed for slicing operation with different configuration and mechanisms [52.62, 90–93]. Such saws rely on the abrasives (typically industrial diamond) impregnated along the circumferential surface of a wire for slicing. The saws can be classified into rotary or reciprocating (linear) motions. Conceptually, this type of saws is akin to the ID saw because the diamond-impregnated wiresaw is essentially an ID saw with a linear instead of an annular cutting edge.

Fundamentally, however, the manufacturing process model of such saws is entirely different from that of the slurry wiresaw. This type of saw with diamond-impregnated wires removes materials by means of a ploughing process – a more brutal machining process than the rolling-indenting free abrasive machining process of the slurry wiresaw. In addition, the abrasive grits on the surface of a wire can be easily stripped off, leading to the loss of the ability for the wire to perform further slicing operations.

52.2.4 Others

As mentioned earlier in Sect. 52.1.2, as-sliced wafers can be ground first, followed by epitaxial growth process to produce wafers ready for device fabrication. In other cases, circular saws with the circumferential outer edge coated with diamond abrasive grits are also employed in slicing. This type of slicing tool is normally used for small samples, and typically is subject to a large degree of vibration and inaccuracy of surface finish.

52.2.5 Comparison of Slicing Technology

Modern wiresaw manufacturing is based on the so-called *free abrasive machining* (FAM) process with rolling-indenting, which removes materials via third-party free abrasives in slurry [52.1]. In contrast, the conventional inner diameter (ID) saw is based on the *ploughing machining* process which is characterized by the removal of materials with forceful media attached to the tool. The two schematics in Figs. 52.4 and 52.5 contrast these two manufacturing processes and arrangements.

The conventional ID saw in Fig. 52.4 cuts through the ingot to obtain one slice of wafer each time with an annular cutting blade stretched and held in high tension. The blade rotates at very high speed while feeding onto the ingot to cut through ingot with its diamond-coated inner edge. Analysis of stress and vibration in the ID saw with annular blades has been presented [52.75, 76, 94].

As shown in Fig. 52.5, and later in Fig. 52.9, the wiresaw consists of one wire moving either unidirectionally or bidirectionally on the surface of crystal ingot.

The single wire is wound carefully on the wire guides with grooves of constant pitch to form a *wire web*, as shown in Fig. 52.5. The wire guides are rotated by a pair of master-slave drives, causing the entire wire web to move at high speed while carrying the abrasive slurry to remove material from the surface of ingot. The ingot is fed in the downward direction perpendicular to the wire web as shown in Fig. 52.5. The wire is maintained at constant tension during the cutting process. A spool of cold-drawn steel wire is used to continuously supply the wire necessary for cutting.

Depending upon the process control, parallel wire marks may be visible on the wafer surface after they are sliced. Typical surface of a wafer sliced by wire-saw resembles that of a lapped wafer. The wiresaw is capable of slicing wafers of large diameter as long as the distance between the wire guides is larger than the diameter of the ingot. With a wire web consisting of 200–400 strands of wound wire, a total of 200–400 wafers are produced simultaneously once the wire has finished traversing through the ingot. Typical kerf loss is the sum of the diameter of the wire, size of abrasives, and vibration amplitude of wire. The thickness of the wafer is controlled by the pitch of the grooves on the wire guides.

Comparison Between Modern Wiresaw and ID Saw

Comparisons of various properties between the modern wiresaw and ID saw are offered in Table 52.6. From the table, it is clear that the wiresaw has much higher throughput and yield with less kerf loss and surface damage. The wiresaw has found gradually increasing usage in slicing 200 mm and 300 mm single-crystalline silicon wafers and various shapes of polycrystalline

Table 52.6 Comparisons of various properties between the modern slurry wiresaw and ID saw. The comparison suggests that the wiresaw is a more favorable tool for slicing of large quantities of wafers with better surface quality than the ID saw

Property	Wiresaw	ID saw
Manufacturing process model	FAM/lapping	Ploughing/grinding
Typical cut surface features	Parallel wire marks	Chipping and fracture
Depth of damage	Uniform, 5–15 μm	Variable, 20–30 μm
Productivity (typical)	110–220 cm ² /h	10–30 cm ² /h
Total time per run	5–8 h (depending on ingot size)	About 15 min for each slice
Wafers per run	200–400 wafers	One wafer
Kerf loss	180–210 μm	300–500 μm
Minimum thickness of wafer	200 μm (typical)	350 μm
Maximum ingot diameter	300 mm or higher	Up to 200 mm

Table 52.7 Comparisons between the modern slurry wiresaw and the saw with diamond-impregnated wires. The comparison suggests that wiresaw is a more favorable tool for most slicing operations, while the saw with diamond-impregnated wires can be quite effective for slicing very hard wafers with small size

Property	Slurry wiresaw	Saw with diamond-impregnated wires
Manufacturing process model	FAM with rolling-indenting	Ploughing
Abrasive grits	Free abrasive; rejoin cutting proc.	Lost forever once stripped off surface
Depth of damage	Uniform, 5–15 μm	Variable, 20–30 μm
Cost of consumables	Lower (per wafer)	Higher (per wafer)
Slicing very hard wafers	Not very effective	Very effective
Kerf loss	180–210 μm	250–400 μm

wafers with thickness as small as 200 μm for photovoltaic applications. The wiresaw can also be employed to slice highly anisotropic crystals and other materials such as alumina (Al_2O_3) and quartz.

Comparison Between Modern Wiresaw and Saw with Diamond-Impregnated Wires

It is important to note that the modern slurry wiresaw is entirely different from the saw with diamond-impregnated wires in which the diamond grits coated on the surface of wire are used to remove the materials by the shear-dominated process similar to the orthogonal machining process [52.90, 91]. Table 52.7 contrasts the wiresaw and saws with diamond-impregnated wires, showing that the wiresaw is suitable for general slicing operations, while saws with diamond-impregnated wires can be effective in slicing very hard or specialized wafers with small sizes.

52.2.6 Wafer Manufacturing for Large Wafers

After slicing wafers by wiresaw, the subsequent process is flattening to achieve a higher degree of parallelism and flatness of the wafer [52.2, 10, 19, 57, 74]. Both grinding and lapping are conventionally used for this process. Polishing is the next process to obtain a smoother wafer surface.

For the production of large, 300 mm silicon prime wafers using modern wiresaw for electronics fabrication, however, a special challenge with surface waviness of different wavelengths, known as the *nanotopography*, warrants special consideration. Such waviness across the surface of the large wafer is not easily dealt with using the conventional lapping operation because of the elasticity of the large wafer, causing the waviness to be flattened as the lapping tool is applied. Surface grinding, therefore, has become an attractive alterna-

tive for the initial removal of such surface waviness and roughness after slicing.

The nanotopography is illustrated in Fig. 52.6, as defined by SEMATECH. In the figure, different ranges of surface features are identified and categorized for the sake of distinguishing one from the other. Nevertheless, nanotopography and waviness, with amplitudes of surface roughness and wavelengths of waviness shown in Fig. 52.6, are typically found in large wafers.

Grinding in Wafer Manufacturing

After wafers are sliced by wiresaw, grinding is often employed for large wafers for flattening [52.66, 95, 96]. The advantages of grinding over lapping are (1) fully automatic cassette-to-cassette operation, (2) use of a fixed abrasive grinding wheel rather than loose abrasive slurry so the cost of consumables per wafer may be lower, and (3) higher throughput. However, the grinding process cannot entirely remove the waviness induced by wiresaw slicing, which is why grinding cannot totally replace the lapping process.

The grinding operation cannot remove the waviness as effectively as the lapping operation because of elas-

Fig. 52.6 Illustration of surface roughness classified as the *nanotopography* by SEMATECH. Nanotopography and waviness are typically found in large wafers

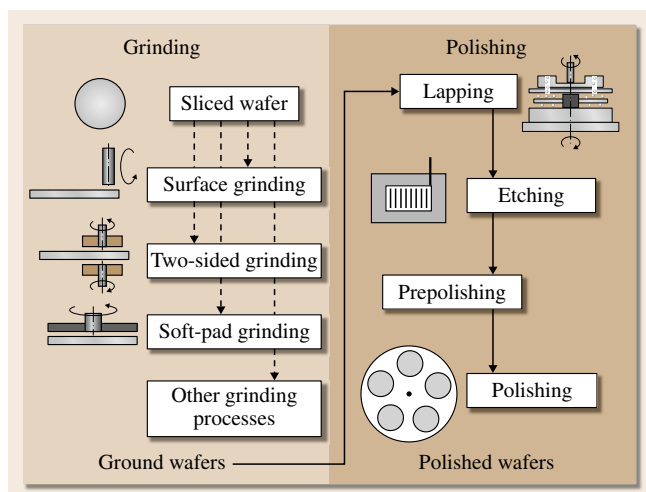

Fig. 52.7 Illustration of revised wafer manufacturing process with the insertion of the grinding operation, especially for very large silicon wafers (Fig. 52.1)

tic deformation of the wafer. When the same total force is applied on a wafer, the elastic deformation of the wafer in lapping is much smaller than that in grinding, resulting in a less pronounced spring-back effect in lapping. The amount of deformation in lapping is only 1/55 to 1/36 of that in grinding [52.77,78,97,98]. In order to improve the removal of surface waviness in grinding operation, several methods have been proposed, including:

1. Wafer grinding followed by a lapping
2. Wax mounting to reduce the effect of elasticity
3. Reduced vacuum
4. Use of a soft pad to avoid elastic spring-back after the grinding operation

A revised wafer production flow is shown in Fig. 52.7 in which the grinding operation follows the slicing operation, followed by the lapping/polishing operations.

52.3 Modern Wiresaw in Wafer Slicing

In the following subsections, the technology of modern slurry wiresaw is introduced with discussions of various topics involved in the technology and research of modern slurry wiresaws.

52.3.1 Definition of Modern Wiresaw

The term *wiresaw* or *modern wiresaw* has been used throughout this chapter to refer to the equipment for slicing crystalline ingots using a bare wire (typically cold-drawn steel wire) pressing onto the ingot with the continuous supply of abrasive slurry at the cutting interface. This is to distinguish them from saws that cut into materials with diamond-impregnated wires under various arrangements such as rotary or prismatic reciprocating motions. In a typical arrangement of a slurry wiresaw, a wire web is formed with a single bare steel wire drawn from a supply spool by winding it along grooved cylindrical wire guides, as illustrated in Fig. 52.5. Although the alternative name *multiwire saw* is also used in the literature, this is potentially misleading because modern wiresaw equipment actually operates on a *single* wire wound on grooved cylindrical guides. In addition, multiple wires are often used in diamond-impregnated reciprocating saw, which could be more appropriately called a *multiwire saw*. Since

separating materials with wire under a similar principle is a century-old technology when wire was used to slab stones in the 19th century, the term *modern wiresaw* has been adopted in this chapter and used interchange-

Fig. 52.8 Picture of a HCT wiresaw. The circled region indicates the wire web formed by the single wire winding over the grooved wire guides. To the upper right of this region is the ingot mounted on the jig, which is controlled to move downwards for slicing operation (source: HCT Inc., and GT Equipment Inc.)

Table 52.8 Operating parameters and their ranges and/or values for wiresawing

Parameter	Values and ranges
Speed of wire	5–15 m/s
Duty cycle of wire	Continuous feeding or reciprocating
Wire tension	25–35 N
Diameter of wire	150–175 μm
Wire bow angle	2–5 $^{\circ}\text{C}$
Kerf loss	180–210 μm (typically)
Slurry, carrier fluid	Water soluble or oil based
Slurry, abrasive grits	Silicon carbide (usually)
Feed rate of ingot	100–300 $\mu\text{m}/\text{min}$
Consumables	Wire and slurry

ably with *wiresaw*. The modern wiresawing is a much more rigorous process than the stone-slabbing operation using wire, and also is subject to more stringent requirements on surface finish for typical applications.

A typical industrial wiresaw is shown in Fig. 52.8, in which four wire guides are shown with a wire web face circled in the figure. A silicon ingot is shown to be fed top-down onto the top horizontal face of the wire web for slicing. To the left are the control console of the wiresaw and the wire management unit which controls the tension of the wire and manages the supply, feeding, tension, and speed of the wire.

52.3.2 Modern Wiresaw Technology

The *modern wiresaw* and associated technology discussed in this chapter utilizes a steel wire with abrasive slurry, consisting of abrasive grits suspended in carrier fluid, for the purpose of slicing crystals. Wire saws had been used in the 19th century in Europe to slab stones. Modern wiresaws, however, are employed to produce wafers with more stringent requirements of surface quality (Fig. 52.3). A typical modern wiresaw, as shown in Fig. 52.8, consists of three main components:

1. Wire management unit
2. Control and program console
3. The slicing compartment, where the ingot is sliced by feeding it onto the wire web

The slicing process of the modern slurry wiresaw belongs to the category of *free abrasive machining (FAM)*. Modern wiresaws utilize a steel wire, under high tension, moving at high speed on the surface of

Fig. 52.9 Three-dimensional illustration of the rolling-indenting process in the wiresaw slicing process in which abrasive grits rolls and indents on the contact interface to remove materials from the substrate surface. This body abrasion process is also called *free abrasive machining (FAM)*

the substrate submerged in abrasive slurry. The wire maintains a bow angle with the cutting surface, applying a normal load along the direction of cutting. Typical parameters of wiresaw and operating parameters are summarized in Table 52.8. A schematic drawing of the modern wiresaw is shown in Fig. 52.5 with the *rolling-indenting* process shown in Fig. 52.9. The *FAM* process of wiresaw slicing with slurry is theoretically less brutal than cutting with fixed abrasive grinding processes [52.90, 91], under the condition of the same energy input, because of the inherent cutting mechanism of rolling and indenting. The cutting interface in Fig. 52.9 is exaggerated for the illustration of free abrasive grits interacting with the substrate surface in rolling and indenting due to the speed differential within the film of fluid trapped between the wire and the substrate surface. Chips are removed from the surface of the work material as a result of repeated rolling-indenting with typical micro- and nanoindentation effects.

52.3.3 Modeling and Control of the Modern Wiresawing Process

Research and studies of the modern wiresaw slicing process started to appear in the 1990s, first in patent disclosures followed by academic and industrial research. Academic-industrial-governmental synergy is characteristic of such research due to the very nature of process modeling for the wiresaw process, which requires a high degree of collaboration in order to make research results

Fig. 52.10 SEM micrographs at scales of $10\ \mu\text{m}$ and $20\ \mu\text{m}$ illustrating the typical surface of an as-sliced wafer. The wafer surface shown here is from a polysilicon material sliced by an industrial wiresaw. The surface is full of random pits resulting from the rolling-indenting manufacturing process. Such a surface is very representative of wafers sliced by wiresaw under normal operating conditions

relevant. In the following subsections, a brief survey of various aspects of research and studies in wiresaw manufacturing processes is presented. Readers are referred to the bibliography at the end of this chapter for further reading.

SEM Study of Surface Characteristics of Wiresawn Wafers

Figure 52.10 shows a typical surface of an as-sliced wafer cut by an industrial wiresaw. The material of the wafer is polysilicon with rectangular surface area, to be used as a PV cell. As can be observed in the scanning electron microscopy (SEM) photo to the left with the scale bar of $20\ \mu\text{m}$, the surface is covered with a random pattern of pits caused by the rolling-indenting process. The abrasive grits used are silicon carbide 400 with an average grit size of $17\ \mu\text{m}$. A more detailed photo on the right with a scale bar of $10\ \mu\text{m}$ shows magnified patterns of random pits, with very little or nearly no fracture, as opposed to typical surface of wafers sliced by ID saws which are populated with more visible fractures on the surface.

The Rolling-Indenting Process Model

Figure 52.10 illustrates the *rolling-indenting* manufacturing process model for slicing using a wiresaw. A three-dimensional (3-D) illustration of the rolling-indenting process associated with free abrasive machining is shown in Fig. 52.9. For more details on the rolling-indenting model, readers are referred to [52.1, 13, 23, 48].

Hydrodynamic and Elastohydrodynamic Interaction

It is known that even in a lubricated wire drawing manufacturing process, the hydrodynamic effect is present. In the wiresaw machining process, the wire moving with high speed (Table 52.8) in a slurry-rich environment will induce not only the hydrodynamic effect but also elastic interaction with the steel wire. The intertwined effects result in the elastohydrodynamic phenomenon common in the modern wiresaw process. In the initial study of such phenomena [52.23], hydrodynamic process modeling and computer simulation were implemented with realistic process parameters. Later, other work also addressed and advanced this topic [52.21, 24, 39, 40]. The hydrodynamic film between the wire and substrate surface supports and suspends the normal force applied to the ingot. The contact interface through the hydrodynamic film generally supports the free abrasive machining with abrasive grits rolling and indenting on the surface of substrate. In some areas, there may be intermittent direct contact made due to the thickness of the slurry film. In [52.50], the author suggested that direct contact may be a more regular occurrence.

Vibration of the Wire in Slicing Using a Wiresaw

Vibration analysis of a stationary wire is a century-old problem with well-known solution (for example, in a stringed musical instrument). The eigenvalue problem and solution of the analysis of vibration of a moving string, however, was only solved in the early 1990s, although the differential equation of motion was first

proposed around 1970. Excessive vibration of the wire during slicing will increase the kerf – an undesirable effect. The application of eigenvalue problems of the moving wire in the wiresawing process has been presented in [52.7, 9, 20, 22, 31, 40].

Consumables in Wiresawing Process

The consumables of wiresawing process include the abrasive grits, carrier fluid, and wire. In recent years, recovery and regeneration of abrasive grits have received considerable attention due to environmental concerns. Several pieces of equipment that recycle abrasive grits have been constructed to recover a large percentage of grits. The carrier fluid has typically become water soluble instead of oil based. Wire used in wiresawing process is made of steel in a cold-drawn process, and is rather inexpensive with very consistent quality. Wires are typically discarded after each slicing operation. In

the future, it is expected that more attention will be paid to the management of these consumables due to environmental concerns.

Material-Related Subjects and Thermal Issues

Wafer slicing also depends on the materials of the crystalline ingots. It may generally be fine to assume isotropy for consideration of slicing materials such as polysilicon; however, highly anisotropic materials such as lithium niobate will display specific behavior based on its anisotropy. Even single-crystalline silicon is anisotropic, although not to the extent seen in lithium niobate. Some recent work with consideration of materials properties can be found in, e.g., [52.38, 42, 43].

Thermal issues and correlation to the surface waviness of large wafers sliced by wiresaw have attracted much attention. Studies have been performed, resulting in disclosures such as [52.51, 52, 69].

52.4 Conclusions and Further Reading

The advent of the modern wiresaw as a generic wafer slicing tool has brought about a revolution in the wafer manufacturing industry, particularly in the silicon wafering industry. As a result of the versatility and capabilities of the modern wiresaw, it has entirely replaced the ID saw technology that from the 1970s to 1990s was the primary slicing tools for wafer production. Equipped with better control and monitoring of industrial processes and research knowledge base of wiresaw process modeling and control, today's industrial wiresaws are gradually becoming the primary tool of choice for slicing.

In this chapter, modern wafer manufacturing and wafering process was discussed and illustrated. Wafer production, based on the collection of operations shown in Fig. 52.1, produces prime wafers from crystalline ingots. Slicing is the first postgrowth wafer-forming

process. Several technologies of slicing were discussed with historical perspectives. The modern slurry wiresaw and its technological development with research in process modeling to improve understanding and control of the process were also presented. Surveys of various topics in wiresaw processing and research include: modeling and control of modern wiresawing process, SEM study of surface characteristics of wiresawn wafers, the rolling-indenting process model, hydrodynamic and elastohydrodynamic interaction, vibration of wire in slicing using wiresaw, consumables in the wiresawing process, and material-related subjects and thermal issues.

Various references to research literature and patents are cited throughout the chapter. The list of references provides readers with suggestions for further reading on topics of their interests.

Acknowledgements

A.1 Crystal Growth Techniques and Characterization: An Overview by Govindhan Dhanaraj, Kullaiiah Byrappa, Vishwanath (Vish) Prasad, Michael Dudley

The authors would like to thank Dr. Kedar Gupta and Dr. Rick Schwerdtfeger for their generous support and encouragement during the preparation of this manuscript.

We also wish to acknowledge the help rendered by Ms. K. Namratha, Dept. of Geology, University of Mysore, Mysore, India in preparing this chapter.

A.4 Generation and Propagation of Defects During Crystal Growth by Helmut Klapper

The author is indebted to J. Thar and R.A. Becker (Institut für Kristallographie, RWTH Aachen University) for the preparation of the figures.

A.6 Defect Formation During Crystal Growth from the Melt by Peter Rudolph

The author is indebted to his long-term co-workers Dr. M. Neubert, Dr. F.-M. Kießling, Dr. C. Frank-Rotsch, Dr. U. Juda, M. Czupalla, P. Lange, O. Root, U. Kupfer, M. Ziem, T. Wurche, M. Imming, U. Rehse, W. Miller (all from IKZ Berlin), and the director of IKZ Prof. R. Fornari for helpful discussions, and experimental work essentially contributing to the present chapter. He is also grateful for long-term stimulating cooperations with Dr. M. Jurisch, Dr. B. Weinert, and Dr. S. Eichler from Freiburger Compound Materials GmbH. Special thanks go to D. Bliss from the Air Force Res. Lab. (USA) for critical reading and helpful comments for manuscript revision.

B.7 Indium Phosphide: Crystal Growth and Defect Control by Applying Steady Magnetic Fields by David F. Bliss

The author would like to thank Prof. Michael Dudley for helpful guidance in x-ray topography and

crystallographic analysis, G.G. Bryant and R. Lancto for their skilled assistance in crystal growth and data acquisition, and Dr. G. Iseler for many discussions. Topography was carried out at the Stony Brook Synchrotron Topography Facility, beamline X19C, at the National Synchrotron Light Source, at Brookhaven National Laboratory, which is supported by the US Department of Energy. This research effort was supported by the US Air Force Office of Scientific Research.

B.9 Czochralski Growth of Oxide Photorefractive Crystals by Ernesto Diéguez, Jose Luis Plaza, Mohan D. Aggarwal, Ashok K. Batra

The authors gratefully acknowledge the support of the present work through NSF RISE grant # HRD-0531183. Special thanks are due to Mr. G. Sharp for fabrication of crystal growth system components. One of the authors (M.D.A.) would like to acknowledge support from NASA Administrator's Fellowship Program (NAFP) through United Negro College Fund Special Program (UNCFSP) Corporation under their contract #NNG06GC58A.

B.11 Growth and Characterization of Antimony-Based Narrow-Bandgap III-V Semiconductor Crystals for Infrared Detector Applications by Vijay K. Dixit, Handady L. Bhat

The authors are grateful to the collaborators: B. Bansal and V. Venkataraman, Departments of Physics Indian Institute of Science, Bangalore; and B.M. Arora and K.S. Chandrasekaran, Solid State Group, TIFR Mumbai. The authors are also grateful to the many authors whose work is included in this review.

B.13 Laser-Heated Pedestal Growth of Oxide Fibers by Marcello R.B. Andreetta, Antonio Carlos Hernandez

The authors would like to thank the Brazilian agencies CNPq, FAPESP, and CAPES for financial support

and also all the editors and journals that kindly allowed the reproduction of the figures that illustrate this chapter.

B.14 Synthesis of Refractory Materials by Skull Melting Technique

*by Vyacheslav V. Osiko, Mikhail A. Borik,
Elena E. Lomonova*

We wish to thank the following for help in the preparation of this chapter: Dr. O. M. Borik, Dr. V. A. Panov, and S. Semyova.

C.17 Bulk Single Crystals Grown from Solution on Earth and in Microgravity

*by Mohan D. Aggarwal, Ashok K. Batra,
Ravindra B. Lal, Benjamin G. Penn,
Donald O. Frazier*

The authors are grateful for helpful discussions with a number of graduate students and other physics faculty in the Department of Physics at Alabama A&M University. Authors are thankful to Garland Sharp for his expert machining work and Jerry Johnson for his glass-blowing jobs in the design of various crystal growth systems described in this work. Spacelab-3 and IML-1 work was supported by NASA contracts. The optical holography work for these experiments was developed in collaboration of Dr. James Trolinger of MetroLaser, Inc. This work was partially supported under NSF-HBCU RISE program HRD-0531183 and US Army Space and Missile Defense Command, Contract W9113M-04-C-0005. Two of the authors (M.D.A. and R.B.L.) would like to acknowledge support from NASA Administrator's Fellowship Program (NAFP) through United Negro College Fund Special Programs (UNCFSP) Corporation under their Contract No. NNG06GC58A.

C.18 Hydrothermal Growth of Polyscale Crystals

by Kullaiah Byrappa

The author wishes to acknowledge Prof. M. Yoshimura (Tokyo Institute of Technology, Japan), Prof. Richard E. Riman (Rutgers University, USA), Prof. Yan Li (Tsinghua University, China), Prof. T. Adschiri, and Prof. Dirk Ehrentauf (Tohoku University, Japan) for providing photographs of crystals synthesized by them and also some fruitful discussion. Thanks are also due to my group members Prof. B. Basavalingu,

Prof. K.M. Lokanatha Rai, and Prof. S. Ananda of Mysore University, India, for their assistance in preparing this chapter. The author acknowledges the help of Prof. Xu Haiyan, Anhui Institute of Architecture and Industry, Hefei, China, for providing some of the latest literature on solution processing of materials, and also for careful reading and constructive comments on this chapter. Also the authors acknowledge the help rendered by Dr. Jürgen Riegler, Tohoku University, Japan, in reading this manuscript and useful comments.

C.19 Hydrothermal and Ammonothermal Growth of ZnO and GaN

by Michael J. Callahan, Qi-Sheng Chen

The authors acknowledge collaborators whose work either influenced or was explicitly incorporated into this article. Special thanks are due to Govindhan Dhanaraj (SUNY-Stony Brook) who provided expertise on synchrotron white-beam x-ray topographs and to Dr. Buguo Wang (Solid State Sciences Corporation), Dr. Michael Alexander, Dr. David Bliss, and Michael Suscavage (Air Force Research Laboratory) for their expertise and many discussions with the authors on ammonothermal and hydrothermal research.

Finally, we thank the Air Force Office of Scientific Research (Drs. Jerry Witt, Dan Johnstone, Todd Steiner, and Don Silversmith) and the Naval Research Lab (Dr. Colin Wood) for their past and current support of research on wide-bandgap semiconductors.

C.20 Stoichiometry and Domain Structure of KTP-Type Nonlinear Optical Crystals

by Michael Roth

The author is grateful to Dr. N. Angert and Dr. M. Tseitlin for their long-term collaboration and numerous discussions on the science and technology of KTP-type crystals as well as for providing some crystal and domain photographs.

C.21 High-Temperature Solution Growth: Application to Laser and Nonlinear Optical Crystals

*by Joan J. Carvajal, Maria Cinta Pujol,
Francesc Díaz*

The authors thank to our colleague Prof. Magdalena Aguiló for her relevant contribution specially in structural and crystallographic aspects. This work was

supported by the Spanish Government under projects MAT2008-06729-C02-02/NAN and the Catalan Authority under project 2009SGR235. J.J. Carvajal and M.C. Pujol are supported by the Education and Science Ministry of Spain and European Social Fund under the Ramon y Cajal program, RYC2006-858.

C.22 Growth and Characterization of KDP and Its Analogs

by Sheng-Lai Wang, Xun Sun, Xu-Tang Tao

We wish to thank the following for help in the preparation of this chapter and for helpful discussions: Bing Liu, Xiao-Min Mu, Bo Wang, Yong-Qiang Lu, Liang Li, Prof. Chang-Shui Fang, Prof. Xin-Guang Xu (Shandong Univ., Jinan, China), Dr. Natalia Zaitseva, and Dr. Jim De Yoreo (LLNL). The authors also wish to thank Dr. Govindhan Dhanaraj for critically reading the manuscript and helpful discussion.

D.24 AlN Bulk Crystal Growth by Physical Vapor Transport

by Rafael Dalmau, Zlatko Sitar

This work was supported by the DoD Multidisciplinary University Research Initiative (MURI) administered by the Office of Naval Research (ONR) under grant N00014-01-1-0716, monitored by Dr. C.E. Wood.

D.26 Growth of III-Nitrides with Halide Vapor Phase Epitaxy (HVPE)

by Carl Hemmingsson, Bo Monemar, Yoshinao Kumagai, Akinori Koukitu

The authors gratefully acknowledge contributions from P.P. Paskov, T. Paskova, and V. Darakchieva, concerning new data cited and some illustrations. Our collaboration with the Epigress/Aixtron company (F. Wischmeyer, M. Heuken) in development of HVPE growth procedures and related equipment has been most helpful. We also have benefiting from a collaboration with A. Usui at Furukawa KK.

D.27 Growth of Semiconductor Single Crystals from Vapor Phase

by Ramasamy Dhanasekaran

The author is highly grateful to his research co-workers Dr. O. Senthil Kumar, Dr. S. Soundeswaran, Dr. M. J. Tafreshi, Dr. E. Varadarajan, Dr. P. Prabukanthan, and K. Senthilkumar for useful discussions and

support in understanding the concepts presented in this chapter. Thanks are also due to Dr. B. Vengatesan and Dr. K. Balakrishnan, who initiated the vapor growth activities at Crystal Growth Centre, Anna University. The help rendered by R. Arunkumar, G. Bhagyaraj, T. Shabi, and M. Senthil Kumar in preparing this manuscript is duly acknowledged.

E.28 Epitaxial Growth of Silicon Carbide by Chemical Vapor Deposition

by Ishwara B. Bhat

The author would like to thank Canhua Li and Rongjun Wang for carrying out a major portion of the work described herein as part of their Ph.D. theses. Financial supports from DARPA contract #DAAD19-02-1-026 and the ERC program of the NSF are acknowledged.

E.30 Epitaxial Lateral Overgrowth of Semiconductors

by Zbigniew R. Zytkiewicz

The author thanks Dr. D. Dobosz for her assistance in the LPE growth of the ELO structures, Dr. E. Papis and K. Babska for the photolithography and processing of the substrates, and Dr. J. Domagala for XRD analysis of the samples. Contributions of Prof. T. Tuomi, Prof. P. McNally, Dr. R. Rantamaki, and Dr. D. Danilewsky to synchrotron x-ray topography experiments and Dr. A. Rocher to TEM studies of the GaAs structures are highly appreciated. The author is also very grateful to Prof. S. Dost for his valuable comments and feedback. This work was carried out with partial financial support from the Polish Committee for Scientific Research under grant 3T08A 021 26. Partial support from the Natural Sciences and Engineering Research Council of Canada (NSERC) is also gratefully acknowledged.

F.37 Vapor Growth of III Nitrides

by Dang Cai, Lili Zheng, Hui Zhang

This work was supported by the DOD Multidisciplinary University Research Initiative (MURI) program administered by the Office of Naval Research under Grant N00014-01-1-1-0716 monitored by Dr. Colin E. Wood. We would like to express our gratitude to Drs. Williams Mecouch and Zlatko Sitar from North Carolina State University for providing experimental data.

H.47 Protein Crystal Growth Methods

*by Andrea E. Gutiérrez-Quezada,
Roberto Arreguín-Espinosa, Abel Moreno*

One of the authors (Abel Moreno) thanks CONACYT (Mexico) project No. 82888 for sponsorship. Roberto Arreguín-Espinosa acknowledges financial support from the project DGAPA-UNAM, No. IN210007. Andrea E. Gutiérrez-Quezada acknowledges scholarship from SNI-CONACYT.

H.48 Crystallization from Gels

by S. Narayana Kalkura, Subramanian Natarajan

The authors wish to thank Dr. E.K. Girija, S.A. Martin Britto Dhas (Madurai Kamaraj University, India), Dr. George Varghese (St. Berchmans College, Mahatma Gandhi University, India), and Dr. V. Jayanthi (Stanley Medical College, Chennai, India) for all their help in preparing this chapter. S.N.K. thanks AICTE and UGC, India for financial assistance for carrying out majority of the work reported in the review. S.N. thanks the UGC for the SAP funding to his Institution.

H.49 Crystal Growth and Ion Exchange in Titanium Silicates

*by Aaron J. Celestian, John B. Parise,
Abraham Clearfield*

Support for this work was provided by NSF-CHE-0221934 (CEMS) and DMR-051050 to John B. Parise and NSF-EAR programs. A. Clearfield would like to acknowledge the Department of Energy (DOE) through DE-FG07-01ER63300 and Westinghouse Savannah River Technology Center. We acknowledge the support of the Advanced Photon Source, Argonne National Laboratory, the National Synchrotron Light Source, Brookhaven National Lab-

oratory, the National Institute of Standards and Technology, U.W. Department of Commerce, and the ISIS facility at the Rutherford Appleton Laboratory in providing the neutron research facilities used in this work.

H.50 Single-Crystal Scintillation Materials

by Martin Nikl, Anna Vedda, Valentin V. Laguta

Authors are indebted to K. Nejezchleb, C. W. E. van Eijk and Xue-Jian Liu for providing material for Figs. 50.12, 50.17, 50.29 and 50.30, respectively, M. Dusek for preparation of figures of material structures, P. Bohacek, K. Nejezchleb, N. Senguttuvan, and A. Novoselov for information about crystal growth, E. Jurkova for the help in manuscript preparation, and C. R. Stanek for useful comments and linguistic corrections. Financial support of Czech GACR 202/05/2471, GA AV S100100506, KAN300100802 and Italian Cariplo foundation projects is gratefully acknowledged.

H.52 Wafer Manufacturing and Slicing Using Wiresaw

*by Imin Kao, Chunhui Chung,
Roosevelt Moreno Rodriguez*

The authors wish to thank Professor Vish Prasad, who has been instrumental in the collaboration of this research on wiresaw slicing and wafer manufacturing. His enthusiasm has always been an inspiration. Several industrial collaborators include Dr. Kedar Gupta, John Talbott, and others. The lead author would also like to thank his previous students who work in wiresaw manufacturing: Drs. Milind Bhagavat, Songbin Wei, Liqun Zhu, and Sumeet Bhagavat, and Mr. Abhiram Govindaraju. The research has been supported by various National Science Foundation (NSF) grants and the United States Department of Energy (DoE) grants.

About the Authors

Francesco Abbona

Università degli Studi di Torino
Dipartimento di Scienze Mineralogiche
e Petrologiche
Torino, Italy
francesco.abbona@unito.it

Chapter A.3

Professor Francesco Abbona received the MSc in Chemistry from the University of Torino, where he is now Full Professor of Mineralogy. His first research was devoted to minerals of the Alps, then he has done research mainly on the relationship between crystal morphology and crystal structure and nucleation and evolution of crystals from aqueous solutions. He is also interested in historical crystallography.

Mohan D. Aggarwal

Alabama A&M University
Department of Physics
Normal, AL, USA
mohan.aggarwal@aamu.edu

Chapters B.9, C.17

Mohan Aggarwal is a Professor and Chair of the Physics Department at Alabama A&M University. He earned his PhD degree in physics from Calcutta University in 1974 and did his post doctoral work at Pennsylvania State University. He has extensive experience in the bulk crystal growth and characterization of a variety of organic and inorganic nonlinear optical crystals, piezoelectric materials and scintillator materials using the solution and melt growth techniques. He is the author or coauthor of more than 204 publications including a few book chapters.

Marcello R.B. Andreeta

University of São Paulo
Crystal Growth
and Ceramic Materials Laboratory,
Institute of Physics of São Carlos
São Carlos, SP, Brazil
marcello@ifsc.usp.br

Chapter B.13

Marcello R.B. Andreeta received his PhD in Materials Science and Engineering from Universidade de São Paulo, Brazil (2001). His research interests include crystal growth, solid-state lasers, Raman and AFM microscopy. Currently he develops new crystalline compounds for optical devices using laser-heated pedestal growth technique at the Crystal Growth and Ceramic Materials Laboratory (IFSC-USP), São Carlos, SP, Brazil.

Dino Aquilano

Università degli Studi di Torino
Facoltà di Scienze Matematiche,
Fisiche e Naturali
Torino, Italy
dino.aquilano@unito.it

Chapter A.3

Professor Dino Aquilano graduated in Physics from Torino University in 1963. From 1974 to 1976 he enjoyed a CNR-NATO fellowship at the CRMC2-CNRS, Univ. Aix-Marseille III. Since 1980 he was an Associated Professor of Mineralogy at the Faculty of Sciences of Torino University. He retired at the end of 2007 and is now a Professor under 3-years contract at the Faculty of Science of Torino University. He has published more than 100 papers on the theoretical and experimental aspects of crystal growth with particular attention to surface microtopography of flat crystal faces, twinning and polytypism as growth phenomena, growth kinetics of crystal faces from pure and impure solutions, and relationships between morphology (equilibrium and growth) and crystal structure.

Roberto Arreguín-Espinosa

Universidad Nacional Autónoma
de México
Instituto de Química
Mexico City, Mexico
arrespin@unam.mx

Chapter H.47

Roberto Arreguín-Espinosa received the Laurea degree in Biology, the MS degree in Marine Biology and the PhD in Biochemistry at Universidad Nacional Autónoma de México. His research activities include the analyses of tridimensional structure of macromolecules with biological interest by means of x-ray, circular dichroism, dynamic light scattering and NMR techniques. He is member of the Protein Society and Mexican Academy of Science since 2002.

Jie Bai

Intel Corporation
Hillsboro, OR, USA
jie.bai@intel.com

Chapter [G.44](#)

Jie Bai received her PhD degree in materials science and engineering from Stony Brook University in 2006. She joined Amberwave Systems the same year. Her research focused on structural characterization and study of semiconductor epitaxial films. Currently, she works as a failure analysis engineer at Intel.

Stefan Balint

West University of Timisoara
Department of Computer Science
Timisoara, Romania
balint@math.uvt.ro

Chapter [F.40](#)

Stefan Balint obtained his PhD in Mathematics in 1976 and is currently a full Professor at the Faculty of Mathematics and Computer Science of the West University of Timisoara, Romania. His research interests include nonlinear dynamics, stability and control with applications in fluid dynamics, material science, aircraft dynamics and artificial neural networks.

Ashok K. Batra

Alabama A&M University
Department of Physics
Normal, AL, USA
ashok.batra@aamu.edu

Chapters [B.9](#), [C.17](#)

Ashok Batra received MTech and PhD degrees from Indian Institute of Technology, Delhi. Currently, he is a faculty member in the Department of Physics at Alabama A&M University. He was a co-investigator on a solution crystal-growth experiment flown aboard NASA-IML-1 space shuttle mission. His research interests include crystal growth, organic solar cells, ferroelectric, pyroelectric, piezoelectric materials and their applications, nano-composites, and nanostructured chemical sensors. He has published more than 80 publications.

Handady L. Bhat

Indian Institute of Science
Department of Physics
Bangalore, India
hlbhat@physics.iisc.ernet.in

Chapter [B.11](#)

Handady L. Bhat obtained his BSc from Mysore University and both MSc and PhD from Sardar Patel University, Gujarat, India. He joined the Physics Department of the Indian Institute of Science, Bangalore as a Research Associate in 1973, and progressed steadily to become a professor in 1993. He was the chairman of this department during 2002-2006. During 2006-2008 he was a CSIR emeritus Scientist and is currently a visiting faculty. He is also a visiting professor at Centre for Liquid Crystal Research, Bangalore. His research interests include crystal growth and physics with special reference to ferroelectric, nonlinear optical, semiconductor and magnetic materials. He has over 200 research publications and is currently the Joint Secretary of Materials Research Society of India.

Ishwara B. Bhat

Rensselaer Polytechnic Institute
Electrical Computer
and Systems Engineering Department
Troy, NY, USA
bhati@rpi.edu

Chapter [E.28](#)

Ishwara B. Bhat is a Professor of Electrical, Computer and Systems Engineering Department at Rensselaer Polytechnic Institute (RPI). He received his BSEE from Indian Institute of Technology, India and his MS and PhD degrees from Electrical Engineering RPI. Bhat joined Rensselaer in 1985 as a research associate and was promoted to full professor in 2000. His research focus is on the epitaxial growth and characterization of several II–VI, III–V, and IV–IV semiconductors. He has published over 100 articles in refereed journals and has served as a member of the program committee of several national and international conferences.

David F. Bliss

US Air Force Research Laboratory
Sensors Directorate Optoelectronic
Technology Branch
Hanscom AFB, MA, USA
david.bliss@hanscom.af.mil

**Chapter B.7**

Dr. David Bliss has been the Program Manager for crystal growth at the Air Force Sensors Directorate's Hanscom Research Site for the past 20 years. He received an SM degree in Materials Science and Engineering from MIT and a PhD from SUNY Stony Brook. He has written over fifty papers for journals and conferences and holds 10 patents. Most recently he has been leading a US Air Force-funded project to develop bulk gallium nitride substrates for GaN lasers and electronics. He is the past president of the American Association for Crystal Growth, and is involved in many aspects of novel crystal development in the US and abroad.

Mikhail A. Borik

Russian Academy of Sciences
Laser Materials
and Technology Research Center,
A.M. Prokhorov General Physics Institute
Moscow, Russia
borik@lst.gpi.ru

**Chapter B.14**

Mikhail A. Borik received the PhD degree in technology of Electronic Materials from the Lebedev Physics Institute of the USSR Academy of Sciences in 1985. He is currently Senior Research Scientist at the Laser Materials and Technology Research Center of A.M. Prokhorov General Physics Institute Russian Academy of Sciences. His scientific interests are in the field of crystal growth of high-temperature oxides, skull melting technique, and the technology of high-temperature glasses.

Liliana Braescu

West University of Timisoara
Department of Computer Science
Timisoara, Romania
lilianabraescu@balint1.math.uvt.ro

**Chapter F.40**

Liliana Braescu obtained her PhD in Mathematics in 2002 and is currently an Associate Professor at the Faculty of Mathematics and Computer Science of the West University of Timisoara, Romania. Her research interests include control theory, stability and domains of attractions with applicability in modelling of the crystal growth processes, blood coagulation, and dental endosteal implantation.

Kullaiah Byrappa

University of Mysore
Department of Geology
Mysore, India
kbyrappa@gmail.com

**Chapters A.1, C.18**

Prof. Byrappa graduated from the University of Mysore, India, with Ranks and Gold Medals. Then he left India during 1977 to pursue PhD work at the Moscow State University, Russia. He is specialized in Crystal Growth and Material Processing using the hydrothermal technique. He has published over 180 research papers in the International Journals, and also authored and edited several. He is the member of the International Commission on Crystal Growth and Characterization of Materials; International Commission on Mineral Synthesis and Interface Processes; Council Member of the Asian Association for Crystallography, Council Member of the Indian National Science Academy Crystallography Association. Prof. Byrappa is a recipient of Sir C.V. Raman Award for 1998 in Physical Sciences, two times recipient of the Golden Jubilee Award of the University of Mysore for the years 1986 and 1992. During 2005, he was awarded the Materials Research Society of India Medal. He is a Fellow of the World Academy of Ceramics. He is leading a hydrothermal research laboratory.

Dang Cai

CVD Equipment Corporation
Ronkonkoma, NY, USA
dcai@cvdequipment.com

**Chapter F.37**

Dr. Dang Cai is an expert in the field of process modeling and equipment design for vapor growth systems. He received his PhD from the Stony Brook University in Mechanical Engineering. Dr. Cai is currently working as a project manager at CVD equipment Corporation, NY, USA. His research interests include III nitrides vapor growth and solar cell related thin film coatings on glass.

**Michael J. Callahan**

Chapter C.19

GreenTech Solutions
Hanson, MA, USA
mjcal37@yahoo.com

Michael Callahan was employed by the United States Air Force Research Laboratory in 1999 and was the Principal Investigator of the High-Pressure Solution Growth Facility located at Hansom AFB, USA from 2004-2008. Mr. Callahan received a MS degree in Electrical Engineering from Western New England College. His research interests include solution growth of large single crystals particularly gallium nitride and multifunctional oxides. He is currently a member of the MRS and SPIE and is active proponent of solvothermal and hydrothermal crystal growth research.

**Joan J. Carvajal**

Chapter C.21

Universitat Rovira i Virgili (URV)
Department of Physics
and Crystallography of Materials
and Nanomaterials (FICMA-FICNA)
Tarragona, Spain
joanjosep.carvajal@urv.cat

Joan J. Carvajal graduated in Chemistry (1997) and received his PhD in Chemistry (2003) from the Universitat Rovira i Virgili. Currently he is Ramon y Cajal Researcher at the same university. He is author of more than 30 ISI papers, and 5 book chapters. His research interests cover synthesis and crystal growth of optical and semiconductor materials at the micro- and nanoscale for photonic applications.

Aaron J. Celestian

Western Kentucky University
Department of Geography and Geology
Bowling Green, KY, USA
aaron.celestian@wku.edu

Chapter H.49

Dr. Aaron Celestian is an Assistant Professor of Mineralogy at Western Kentucky University. He completed his Geology BSc at the University of Arizona, and then finished his MSc and PhD at Stony Brook University. His research interests are in time-resolved molecular-scale characterization of microporous Earth materials and synthetic analogues, with application to the Earth and sciences and industry.

Qi-Sheng Chen

Chinese Academy of Sciences
Institute of Mechanics
Beijing, China
qschen@imech.ac.cn

Chapter C.19

Qi-Sheng Chen graduated and obtained the MS degree both at Department of Mechanics, Peking University and received the PhD degree from the Institute of Mechanics, Chinese Academy of Sciences in 1997. Chen was Faculty administrator and coordinator at the Department of Mechanical Engineering, Florida International University in 2001. Since 2002, Chen has been Research Professor at the Institute of Mechanics, Chinese Academy of Sciences. His research activities include computational fluid dynamics and crystal-growth process modeling.

**Chunhui Chung**

Chapter H.52

Stony Brook University
Department of Mechanical Engineering
Stony Brook, NY, USA
chuchung@ic.sunysb.edu

Mr. Chunhui Chung received his MS degree from the Department of Mechanical Engineering, National Cheng Kung University, Tainan, Taiwan in 2004. He is a PhD candidate in the Department of Mechanical Engineering, Stony Brook University, New York, USA. His research focuses on the wafer manufacturing processes including the wiresaw slicing, lapping, and other relevant topics.

**Ted Ciszek**

Chapter H.51

Geolite/Siliconsultant
Evergreen, CO, USA
ted_ciszek@siliconsultant.com

T.F. (Ted) Ciszek is an experimental physicist with an emphasis on silicon crystal growth and materials science for photovoltaics. He is a retired Principal Scientist at the DOE National Renewable Energy Laboratory (NREL), now operating an independent consulting business, Siliconsultant, a division of Geolite. He holds 25 issued patents with several others pending, and 170 technical journal and proceedings publications.

Abraham Clearfield

Texas A&M University
Distinguished Professor of Chemistry
College Station, TX, USA
clearfield@chem.tamu.edu

Chapter H.49

Abraham Clearfield is a Distinguished Professor of Chemistry at Texas A&M University. He has been awarded both the Southwest and the Northeast Regional ACS awards and received an honorary PhD from Oviedo University, Spain. He discovered the major zirconium phosphate phases that involved him in major contributions to the field of inorganic ion exchange materials and its use in nuclear waste programs.

Hanna A. Dabkowska

Brockhouse Institute
for Materials Research
Department of Physics and Astronomy
Hamilton, Ontario, Canada
dabkoh@mcmaster.ca

Chapter B.12

Hanna Dabkowska received the MS degree in Chemistry from Warsaw University and the PhD degree in Physics from the Institute of Physics Polish Academy of Science in 1983. In 1990 she joined McMaster University as a Research Scientist. Her research interests include crystal growth of oxide materials by different methods. She is a Chair of the Commission of Crystal Growth and Characterization in the International Union of Crystallography and a Member of the Executive Committee of the International Organization for Crystal Growth. She is in author and co-author of more than 91 research papers.

Antoni B. Dabkowski

McMaster University, BIMR
Brockhouse Institute
for Materials Research,
Department of Physics and Astronomy
Hamilton, Ontario, Canada
dabko@mcmaster.ca

Chapter B.12

Antoni Dabkowski has extensive experience in crystal growth of oxide materials with expertise in design, construction, and computerization of crystal growth equipment. He works with techniques such as liquid-phase epitaxy (magnetic garnets, thin films), the Czochralski method and top seeding, growth from high-temperature solutions, directional solidification and Bridgman, as well as optical floating zone. Since recently he has been interested in piezo- and ferroelectric perovskites, thin films of electrically conductive oxides as well as in the influence of substrates on epitaxial film properties. He is author and co-author of more than 45 research papers.

Rafael Dalmau

HexaTech Inc.
Morrisville, NC, USA
rdalmau@hexatechinc.com

Chapter D.24

Rafael Dalmau received the PhD degree in Materials Science and Engineering from North Carolina State University. His research interests are in bulk crystal growth, metalorganic vapor phase epitaxy, and characterization of wide band gap nitride semiconductors. He is currently developing aluminium nitride substrate technology at HexaTech Inc.

Govindhan Dhanaraj

ARC Energy
Nashua, NH, USA
ghanaraj@arc-energy.com

Chapters A.1, D.23, G.42

Dr. Govindhan Dhanaraj is a Chief Scientist and Manager of Crystal Growth Technologies at ARC Energy, Nashua, NH. He was a research faculty at the Department of Materials Science and Engineering, Stony Brook University, NY from 2000 to 2007. He served as a research Assistant Professor at Hampton University, VA until 1999 and specialized in crystal growth of semiconductors and optical materials, epitaxial films and defect evaluation. Dr. Dhanaraj earned a PhD degree from the Indian Institute of Science (Bangalore) and then joined the Rajaramanna Center for Advanced Technology in India as a senior scientist. Based on his accomplishments, he was awarded with the prestigious Extraordinary Ability Category O1 VISA status by the United States BCIS. He is a co-organizer of the Industrial Growth Symposium under the American Crystal Growth Conference in 2009.

Ramasamy Dhanasekaran

Anna University Chennai
Crystal Growth Centre
Chennai, India
rdhanasekaran@annauniv.edu;
rdcgc@yahoo.com

Chapter D.27

Dr. Dhanasekaran is a Professor in Crystal Growth Centre at the Anna University Chennai, India and is working there for the past thirty one years. He obtained his PhD degree in 1986 and did extensive research at Stanford University, USA and University of Nijmegen, The Netherlands. He is the recipient of TANSA award in 2004 and IACG National award-2006. His research interests include nucleation and theories of crystal growth, growth of III–V, II–VI and I–III–VI₂ compounds, NLO and relaxor-ferroelectric single crystals. He has successfully completed several National/International sponsored research projects in the field of crystal growth.

**Ernesto Diéguez**

Universidad Autónoma de Madrid
Department Física de Materiales
Madrid, Spain
ernesto.dieguez@uam.es

Chapter B.9

Ernesto Diéguez (PhD 1983, Madrid) is a Professor of Physics in the Department of Physics of Materials, and Head of the Crystal Growth Lab. His research interest is mainly in crystal growth processes and technology of bulk crystals and thin films. He is currently (2006-2010) Director of the Department of Physics of Materials.

**Vijay K. Dixit**

Raja Ramanna Center
for Advance Technology
Semiconductor Laser Section,
Solid State Laser Division
Indore, India
dixit@rrcat.gov.in

Chapter B.11

Vijay Kumar Dixit obtained his BSc and MSc degrees in Physics from Kanpur University, Uttar Pradesh (UP), India. He obtained his PhD degree from the Department of Physics, Indian Institute of Science, Bangalore, India in 2004. He is working at Raja Ramanna Centre for Advanced Technology Indore, India as a scientist since 2002. During 2008-2009 he was a 21st century Global Center of Excellence (GCOE) fellow at the Department of Materials Science and Engineering, Tohoku University, Japan. His research interests include mainly semiconductor materials science and technology with special reference to photodetector, laser and nanostructures. He has over 30 journal publications and is a member of many professional bodies.

Sadik Dost

University of Victoria
Crystal Growth Laboratory
Victoria, BC, Canada
sdost@me.uvic.ca

Chapter E.29

Dr. Dost is Professor and Canada Research Chair in Semiconductor Crystal Growth, and Director of the Crystal Growth Laboratory at the University of Victoria. He has served as Founding Director of the University Centre for Advanced Materials and Related Technology (CAMTEC) for five years, and also as Chair of the Department of Mechanical Engineering for seven years. His current research combines experimental and theoretical study of crystal growth of semiconducting single crystals. He is well known internationally for his work on liquid-phase electroepitaxy.

Michael Dudley

Stony Brook University
Department of Materials Science
and Engineering
Stony Brook, NY, USA
mdudley@notes.cc.sunysb.edu

Chapters A.1, D.23, G.42, G.44

Dr. Michael Dudley is a Professor of Materials Science & Engineering at Stony Brook University. He obtained his PhD in Engineering from Warwick University, UK in 1982 and then worked as a PostDoc at Strathclyde University, UK. He is an expert in the synchrotron x-ray topography characterization of defects in single crystal materials with a view to understanding their origins.

**Partha S. Dutta**

Chapter B.10

Rensselaer Polytechnic Institute
Department of Electrical, Computer
and Systems Engineering
Troy, NY, USA
duttap@rpi.edu

Dr. Partha S. Dutta is a Professor of Electrical, Computer and Systems Engineering at Rensselaer Polytechnic Institute, Troy, New York. His research interests include semiconductor bulk crystal growth, materials for solid state lighting, photovoltaics, terahertz and nonlinear optical applications, optoelectronic device fabrication and free space optical communication systems. He is a co-founder of Auterra Inc., a company specializing in nanoscale materials.

**Francesc Díaz**

Chapter C.21

Universitat Rovira i Virgili (URV)
Department of Physics
and Crystallography of Materials
and Nanomaterials (FiCMA-FiCNA)
Tarragona, Spain
f.diaz@urv.cat

Francesc Díaz is Full Professor of Applied Physics. Since its foundation in 1996, he has been Coordinator of the Physics and Crystallography of Materials (FiCMA) research group. He is author of 180 ISI papers, 4 books, 3 patents and more than 40 chapters of books. He is currently focussed on nanostructuring of optical materials, spectroscopy and lasing of rare-earth ions in crystalline hosts.

Paul F. Fewster

PANalytical Research Centre,
The Sussex Innovation Centre
Research Department
Brighton, UK
paul.fewster@panalytical.com

Chapter G.41

Paul Fewster has a PhD and DSc from London University, the Paterson Medal from the Institute of Physics, the Industrial Crystallography Award from the British Crystallographic Association, where he is an Honorary Member. He worked in Philips Research from 1981-2002 until he became Head of Research for PANalytical (formerly Philips Analytical). His research interests are in x-ray scattering, including simulation, the influence of the instrument and the reliability of interpretation, for perfect crystalline, distorted layer structures and polycrystalline materials.

Donald O. Frazier

NASA Marshall Space Flight Center
Engineering Technology Management
Office
Huntsville, AL, USA
donald.o.frazier@nasa.gov

Chapter C.17

Donald O. Frazier received his undergraduate degree from Wayne State University and PhD in Physical Chemistry from Rutgers University. He is Chief Scientist for Physical Chemistry at the NASA Marshall Space Flight Center in Huntsville, AL. His research interests include molecular spectroscopy, physical chemistry of solutions, crystal growth, and photonic device materials. He recently co-edited the book "Nonlinear Optics and Applications".

**James W. Garland**

Chapter E.32

EPIR Technologies, Inc.
Bolingbrook, IL, USA
jgarland@epir.com

Dr. Garland received his Physics PhD from the University of Chicago. He was Assistant Professor at the University of California at Berkeley 1954-1958 and Associate Professor 1958-1960 and Professor 1960-1994 at the University of Illinois at Chicago. He has held National Science Foundation and Sloan Foundation fellowships. He joined EPIR in 2005 where his primary interest is II-VI single-crystal multijunction solar cells.

**Thomas F. George**

Chapter F.40

University of Missouri–St. Louis
Center for Nanoscience,
Department of Chemistry
and Biochemistry,
Department of Physics and Astronomy
St. Louis, MO, USA
tfgeorge@umsl.edu

Professor Thomas F. George received his Ph.D. in Chemistry from Yale University, followed by postdoctoral appointments at MIT and the UC-Berkeley. He then had the following positions: Professor of Chemistry at the University of Rochester, Dean of Science at SUNY-Buffalo, Provost at Washington State University, Chancellor at the University of Wisconsin-Stevens Point, and currently Chancellor at the University of Missouri-St. Louis along with an appointment as Professor of Chemistry and Physics. His research in chemical/laser/materials/nanophysics has led to 700 papers, 5 authored books and 16 edited books. He was elected as a foreign member of the Korean Academy of Science and Technology in 2004 and received an honorary doctorate in physics (“honoris causa”) from the University of Szeged in Hungary in 2008.

Andrea E. Gutiérrez-Quezada

Chapter H.47

Universidad Nacional Autónoma
de México
Instituto de Química
Mexico City, Mexico
30111390@escolar.unam.mx

Andrea Gutiérrez-Quezada completed her BSc of Chemistry at the Universidad Nacional Autónoma de México (UNAM) in 2008 supervised by Professor Abel Moreno. Her research interests include protein evolution studies and biomineralization processes.

Carl Hemmingsson

Chapter D.26

Linköping University
Department of Physics, Chemistry
and Biology (IFM)
Linköping, Sweden
cah@ifm.liu.se

Carl Hemmingsson received the MS and PhD degree from Linköping University in 1991 and 1998, respectively. From 1999 to 2001 he was developing growth of SiC using HTCVD at Okmetic AB. In 2003, he joined the Materials Science Group at Linköping University as a senior researcher and since then, his main interest has been growth of bulk GaN using HVPE.

Antonio Carlos Hernandez

Chapter B.13

University of São Paulo
Crystal Growth
and Ceramic Materials Laboratory,
Institute of Physics of São Carlos
São Carlos, SP, Brazil
hernandes@ifsc.usp.br

Antonio Carlos Hernandez received his PhD in Applied Physics from University of São Paulo (USP) in 1993. He is currently a Full Professor at the Institute of Physics of São Carlos (USP), Brazil. His research interests are mainly in crystal growth, physical properties, dielectric and ferroelectric ceramics, non-crystalline materials and nanostructured materials. He is a researcher of National Council for Scientific and Technological Development (CNPq).

Koichi Kakimoto

Chapter B.8

Kyushu University
Research Institute for Applied Mechanics
Fukuoka, Japan
kakimoto@riam.kyushu-u.ac.jp

Koichi Kakimoto is a Deputy Director and a Professor of the Institute of Applied Mechanics of Kyushu University. He received his PhD in Engineering in 1955 from the Graduate School of Electronic Engineering, University of Tokyo. Previous positions included Researcher at NEC Fundamental Research Laboratories (1985), Visiting Researcher of Université Catholique des Louvain in Belgium (1989), Prof. Kakimoto's research focuses on the effects of external fields on melt flow and crystallization.

Imin Kao

Chapter H.52

State University of New York
at Stony Brook
Department of Mechanical Engineering
Stony Brook, NY, USA
imin.kao@stonybrook.edu

Being the Director of the Manufacturing Automation Laboratory (MAL) at SUNY Stony Brook, Professor Kao conducts research in robotics and manufacturing, MEMS, modeling and diagnosis of manufacturing processes, free abrasive machining, and wafer manufacturing. A member of ASME and IEEE, he also served as an associate editor of IEEE Transactions on Robotics and Automation and Journal of Advanced Manufacturing Systems.

John J. Kelly

Utrecht University,
Debye Institute for Nanomaterials
Science
Department of Chemistry
Utrecht, The Netherlands
j.j.kelly@uu.nl

Chapter G.43

John Kelly received his PhD degree from University College Dublin, Ireland in 1970. He was a research scientist at Philips Research Laboratories in Eindhoven and Hamburg. Since 1987 he has been a Professor of Chemistry at Utrecht University. His interests within the Debye Institute for Nanomaterials Science include surface chemistry, materials science and electrochemistry of metals and semiconductors.

Jeonggoo Kim

Neocera, LLC
Beltsville, MD, USA
kim@neocera.com

Chapter E.35

Dr. Jeonggoo Kim is a scientist with a research background in pulsed-energy deposition processes. He received the DSc degree in Department of Mechanical & Aerospace Engineering from the George Washington University and worked in Naval Research Laboratory in DC. He has extensive experience in oxides and biomedical materials with thin film technologies, especially in multilayer processes including superlattice, combinatorial and large area depositions.

Helmut Klapper

Institut für Kristallographie
Aachen, Germany
klapper@xtal.rwth-aachen.de;
helmut-klapper@web.de

Chapter A.4

Dr. Helmut Klapper is a retired Professor of Crystallography and Crystal Physics. His main research activities are: crystal growth from solutions and melts (the latter mainly organic crystals), studies of crystal defects with imaging methods (mainly x-ray topography) and investigations of phase transitions, twins and domains structure by x-ray topography and optical methods. He has been chairman of the “Commission of Crystal Growth and Characterization of Materials” of the “International Union of Crystallography” (1993-1999).

Christine F. Klemenz Rivenbark

Krystal Engineering LLC
General Manager and Technical Director
Titusville, FL, USA
ckr@krystalengineering.com

Chapter E.31

Dr. Christine K. Rivenbark has a Chemical Engineering degree from Switzerland and a PhD degree in Electronic Engineering from the University of Tokyo, Japan. After working as a Research Engineer at the Swiss Federal Institute of Technology in Lausanne (EPFL), she became Assistant Professor at the University of Central Florida in Orlando, FL. She is co-founder and Managing Director of Krystal Engineering LLC, a company specialized in the development of LPE films and bulk crystals of oxides and semiconductors. She is an elected member of the Crystal Growth Commission of the IUCr and a program committee member of IEEE FCS.

Christian Kloc

Nanyang Technological University
School of Materials Science
and Engineering
Singapore
ckloc@ntu.edu.sg

Chapter D.25

Christian Kloc is a University Professor at the School of Materials Science and Engineering, Nanyang Technological University in Singapore. He received his higher education in chemistry, and earned his PhD in physics from Polish Academy of Sciences. At first in Poland, and later in the University of Konstanz, Germany, he focused on crystal growth of semiconductors. Later in Bell Labs, NJ, USA, and currently in Singapore, his research interests are on technology of new materials.

**Solomon H. Kolagani**

Chapter E.35

Neocera LLC
Beltsville, MD, USA
harsh@neocera.com

Dr. Kolagani is an acknowledged expert in pulsed energy deposition processes and has 20 years experience in several thin film deposition technologies. He has managed over 25 government-funded programs related to complex metal oxides. He received his PhD degree from the Indian Institute of Technology, New Delhi, (1983); he was faculty at the Indian Institute of Science (1983-1990); then he worked at Bellcore (1990-1992) and joined Neocera in 1992. He has more than 50 research publications and holds 7 US Patents.

**Akinori Koukitu**

Chapter D.26

Tokyo University of Agriculture
and Technology (TUAT)
Department of Applied Chemistry
Tokyo, Japan
koukitu@cc.tuat.ac.jp

Akinori Koukitu received his Doctor degree from the Tohoku University in 1981, with Prof. J. Nishizawa. He was a visiting scientist at Max-Planck Institute between 1986 and 1987. He became Associate Professor and Professor of TUAT in 1988 and 2000, respectively. He has worked on vapor phase epitaxy growth of III-V semiconductors, in situ monitoring of crystal growth from vapor, and thermodynamic analysis of semiconductor alloys.

Milind S. Kulkarni

MEMC Electronic Materials
Polysilicon and Quantitative Silicon
Research
St. Peters, MO, USA
mkulkarni@memc.com

Chapter F.38

Dr. Milind Kulkarni is Vice President of Polysilicon and Quantitative Silicon Research, at MEMC Electronic Materials. He holds a doctorate in Chemical Engineering and a master's degree in business administration, both from Washington University in Saint Louis. His interests span various fields of science and engineering relevant in upstream semiconductor and solar silicon processing, along with finance, operations and manufacturing management.

Yoshinao Kumagai

Tokyo University of Agriculture
and Technology
Department of Applied Chemistry
Tokyo, Japan
4470kuma@cc.tuat.ac.jp

Chapter D.26

Yoshinao Kumagai received the Dr. Eng. from the University of Tsukuba in 1996. He was researcher of Texas Instruments Inc. from 1996 to 1999. Then, he moved to Tokyo University of Agriculture and Technology. Since 2004, he has been Associate Professor in the Department of Applied Chemistry. His research interest is mainly crystal growth from the vapor phase.

**Valentin V. Laguta**

Chapter H.50

Institute of Physics of the ASCR
Department of Optical Materials
Prague, Czech Republic
laguta@fzu.cz

Valentin Laguta received the MS degree from Kiev State University, then received the CSc and DrSc degrees (Physics and Mathematics) from the Institute for Problems of Materials Science of the Ukrainian National Academy of Science in 1988 and 2006, respectively. Since 2006, he is the leading senior scientist in the Institute of Physics of the AS CR, Prague. Research activities include defects and radiation-induced phenomena in solids, physical properties of magnetoelectric materials.

**Ravindra B. Lal**

Chapter C.17

Alabama Agricultural
and Mechanical University
Physics Department
Normal, AL, USA
rbal@comcast.net

Dr. Ravindra B. Lal received his MS and PhD degrees in Physics from University of Agra, India in 1958 and 1962 respectively. He is presently an Emeritus Professor of Physics at Alabama A&M University. He has extensive experience of growing crystals from solution, both on ground and in space for infrared detectors and frequency doubling materials. He was the principal investigator of two space shuttle experiments on Spacelab-3 and the First International Microgravity Laboratory in 1985 and 1992 respectively.

Chung-Wen Lan

National Taiwan University
Department of Chemical Engineering
Taipei, Taiwan
cwlan@ntu.edu.tw

Chapter F.36

Dr. Chung-wen Lan is Distinguished Professor of Chemical Engineering at National Taiwan University and General Director of Photovoltaics Technology Center at Industrial Technology Research Institute. He is also Chairman of Taiwan Photovoltaic Industry Association. He obtained his PhD degree in Materials Science from the University of Wisconsin at Madison in 1991. He received several awards including the Distinguished Research Awards from the National Science Council of Taiwan and Research Contribution Awards from National Taiwan University for his research contribution to industry. His research interests include crystal growth, photovoltaics, transport phenomena, and computer simulation.

Hongjun Li

Chinese Academy of Sciences
R & D Center of Synthetic Crystals,
Shanghai Institute of Ceramics
Shanghai, China
lh_li@mail.sic.ac.cn

Chapter B.15

Hongjun Li received PhD degree in Materials Science from Shanghai Institute of Optics and Fine Mechanics (SIOM), Chinese Academy of Sciences (CAS). He is currently an Associate Researcher at the Shanghai Institute of Ceramics (SIC), CAS. His research interests are mainly in analysis of crystal defects, numerical simulation of crystal growth systems and optimization of crystal growth techniques.

Elena E. Lomonova

Chapter B.14

Russian Academy of Sciences
Laser Materials
and Technology Research Center,
A.M. Prokhorov General Physics Institute
Moscow, Russia
lomonova@lst.gpi.ru

Elena E. Lomonova received the PhD degree in Technology of Electronic Materials from the Lebedev Physics Institute of the USSR Academy of Sciences in 1980 and a Doctorate in Technology of Electronic Materials from the General Physics Institute of Russian Academy of Sciences in 2001. She was given the Prize of the USSR Council of Ministers in 1991. She is currently Head of Laboratory at the Laser Materials and Technology Research Center of A.M. Prokhorov General Physics Institute Russian Academy of Sciences. Her scientific interests are in the field of crystal growth of high-temperature oxides, skull melting technique, investigation of chemical, physical and mechanical properties of refractory oxides.

Ivan V. Markov

Chapter A.2

Bulgarian Academy of Sciences
Institute of Physical Chemistry
Sofia, Bulgaria
imarkov@ipc.bas.bg

Professor Ivan Markov obtained his PhD degree in Electrochemical Nucleation of Metals in the Institute of Physical Chemistry of the Bulgarian Academy of Sciences, Sofia, where he is at present a Research Professor. From 1992 to 1994 he was with the Department of Materials Science of the National Tsing Hua University, Taiwan, in 1998 with the Department of Condensed Matter Physics of the Universidad Autónoma de Madrid, and in 2004 with the Department of Physics of the Hong Kong University. His research interests are concerned primarily with nucleation and epitaxy. He is author of the textbook "Crystal Growth for Beginners".

Bo Monemar

Chapter D.26

Linköping University
Department of Physics,
Chemistry and Biology
Linköping, Sweden
bom@ifm.liu.se

Bo Monemar obtained his PhD from Lund University in 1971. He was appointed Professor and Head of the Materials Science Division at Linköping University in 1983. He was a member of the IUPAP Semiconductor Commission 1987-1993, and then its secretary 1993-1999. His research covers semiconducting materials, recently mostly III-nitrides. Monemar has published about 1110 papers internationally.

Abel Moreno

Universidad Nacional Autónoma
de México
Instituto de Química
Mexico City, Mexico
carcamo@unam.mx

Chapter H.47

Abel Moreno obtained the BSc in Chemistry at the “Bene meritis” Autonomous University of Puebla (BUAP, Mexico) and the PhD in Chemistry from the University of Granada (Spain). His research activities include crystallogenes, crystallochemistry, biomineralization, and protein crystallography by x-ray diffraction techniques. He has been Professor of Biological Chemistry from 2005 and member of the Mexican Academy of Sciences since 1998.

**Roosevelt Moreno Rodriguez**

State University of New York
at Stony Brook
Department of Mechanical Engineering
Stony Brook, NY, USA
roosevelt@dove.eng.sunysb.edu

Chapter H.52

Roosevelt Moreno Rodriguez is a Fulbright scholar at Stony Brook University, where he is currently a PhD student. His research interests include fingerprint analysis, mathematical modeling of time-frequency analysis, wavelets, intelligent fault detection and diagnostic (FDD) as applied in manufacturing processes. He is a member of the Institute of Electrical and Electronics Engineers (IEEE).

**S. Narayana Kalkura**

Anna University Chennai
Crystal Growth Centre
Chennai, India
kalkura@annauniv.edu

Chapter H.48

Dr. S. Narayana Kalkura is a Professor at the Crystal Growth Centre of Anna University Chennai. He received the MSc and PhD degrees in Physics from the University of Kerala. He joined Anna University as a faculty in 1991. He is an expert in the crystallization of compounds that cause crystal deposition diseases. He was a STA fellow at the National Institute of Biosciences and Human Technology, Tsukuba, Japan (1996-1997) and a staff scientist at the University of Hamburg (2001-2004), specializing in crystallization and structural analysis of biomolecules. His current research interests are on biomineralization and synthesis of nanomaterials for tissue engineering and drug delivery applications.

Mohan Narayanan

Reliance Industries Limited
Gaithersburg, MD, USA
mohan.narayanan@ril.com

Chapter H.51

Srinivasamohan (Mohan) Narayanan joined Reliance Industries Limited as Chief Technology Officer, Solar. Prior to joining RIL, he was the Vice President Technology of Trina Solar based in China and has worked for 17 years at BP Solar, an integrated global PV company. He received his PhD in 1990 from the University of New South Wales, Australia and MS in Materials Science from Case Western Reserve University, Cleveland, USA. He has more than 70 publications and holds a number of patents.

Subramanian Natarajan

Madurai Kamaraj University
School of Physics
Madurai, India
s_natarajan50@yahoo.com

Chapter H.48

Subramanian Natarajan obtained BSc and MSc degrees in Physics from the University of Madras and PhD (1979) from the Madurai Kamaraj University, India. Joining as a Lecturer in the School of Physics of the Madurai Kamaraj University in 1976, he is presently (2008) a Senior Professor and the Chairperson. His major fields of interest are crystallization of small molecules of biological and non-linear optical materials and the crystallography of small molecules.

**Martin Nikl**

Academy of Sciences
of the Czech Republic (ASCR)
Department of Optical Crystals,
Institute of Physics
Prague, Czech Republic
nikl@fzu.cz

Chapter H.50

Martin Nikl graduated in 1982 from Faculty of Nuclear Science and Physical Engineering, Czech Technical University and obtained his PhD in 1986 from the Institute of Physics, Czech Academy of Sciences. Currently, he serves as the Department Head of the Institute of Physics, Academy of Sciences CR. His research interests include luminescence and scintillation mechanism in wide band-gap solids, energy transfer processes and role of material defects in them.

**Vyacheslav V. Osiko**

Chapter B.14

Russian Academy of Sciences
Laser Materials
and Technology Research Center,
A.M. Prokhorov General Physics Institute
Moscow, Russia
osiko@lst.gpi.ru

Vyachslav V. Osiko is Academician, Professor, and Director of the Laser Materials and Technology Research Center of the A.M. Prokhorov General Physics Institute Russian Academy of Sciences. He received the Lenin Prize (1980), the Prize of the USSR Council of Ministers (1991) and R. Laudise Prize from the International Organization of Crystal Growth (1992). He is a member of the Russian Optical Society and a Fellow of the Materials Research Society. His scientific interests are in the field of solid-state physics and technology of materials.

John B. Parise

Chapter H.49

Stony Brook University
Chemistry Department
and Department of Geosciences
Stony Brook, NY, USA
john.parise@stonybrook.edu

Dr. John B. Parise is a joint-Professor in Chemistry and in Geosciences. His expertise is in the area of crystallography and solid-state chemistry. Special interests include the synthesis of novel materials using high-pressure routes, and the characterization of mineral transformation as a function of p , T and time using crystallographic tools on powders and single crystals at synchrotron x-ray and neutron sources.

Srinivas Pendurti

Chapter F.39

ASE Technologies Inc.
Cincinnati, OH, USA
spendurti@asetech.com

Srinivas Pendurti obtained his PhD in 2003 from Stony Brook University, New York. His main research interests are in computational materials science and fluid mechanics. Presently he is based in Cincinnati, USA and works in the gas turbine industry.

**Benjamin G. Penn**

Chapter C.17

NASA/George C. Marshall Space Flight
Center
ISHM and Sensors Branch
Huntsville, AL, USA
benjamin.g.penn@nasa.gov

Benjamin Penn received the PhD in Fiber and Polymer Science from North Carolina State University. He is currently a polymer scientist in the ISHM and Sensors Branch at the NASA/ George C. Marshall Space Flight Center. His research interests include the development of sensors for the detection of chemical agents and structural health monitoring.

**Jens Pflaum**

Chapter D.25

Julius-Maximilians Universität Würzburg
Institute of Experimental Physics VI
Würzburg, Germany
jpflaum@physik.uni-wuerzburg.de

Professor Jens Pflaum is an expert for molecular solid-state physics. He received his PhD from Bochum University in 1999 followed by a postdoctoral fellowship at Princeton University. He continued research on transport phenomena in organic crystals at Stuttgart University 2001-2008. In 2008 he became Professor at Würzburg University and group leader of the Organic Photovoltaics and Electronics division at the ZAE Bayern with focus on molecular optoelectronics.

Jose Luis Plaza

Chapter B.9

Universidad Autónoma de Madrid
Facultad de Ciencias,
Departamento de Física de Materiales
Madrid, Spain
joseluis.plaza@uam.es

Dr. Jose Luis Plaza graduated in Physics at the University Autónoma of Madrid in 1996. He got his PhD in 2000 for his work on GaSb crystal growth. He obtained a postdoc position at the University of Birmingham at the Nanoscale Physics Research Laboratory studying the fabrication of gold nanowires by e-beam lithography. In 2004 he got a Ramon y Cajal Research Position at the Universidad Autónoma de Madrid. Currently his field of research involves oxide and semiconductor crystal growth and nanostructuring surfaces by low energy argon ions.

Udo W. Pohl

Technische Universität Berlin
Institut für Festkörperphysik EW5-1
Berlin, Germany
pohl@physik.tu-berlin.de

Chapter [E.33](#)

Udo W. Pohl studied Physics in Aachen and Berlin, Germany. He obtained his PhD and Venia Legendi from Berlin Institute of Technology, where he is presently COO of the Center for Nanophotonics at the Institute of Solid State Physics. Since 2009 he has been Adjunct Professor of Experimental Physics at Berlin Institute of Technology. He has authored about 200 scientific publications including eight book contributions and two patents. His research focuses mainly on low-dimensional semiconductor epitaxy and spectroscopy.

**Vishwanath (Vish) Prasad**

University of North Texas
Denton, TX, USA
vish.prasad@unt.edu

Chapters [A.1](#), [F.39](#)

Vishwanath “Vish” Prasad is the Vice President for Research and Economic Development at the University of North Texas (UNT). He received his PhD from the University of Delaware, his Master of Technology from the Indian Institute of Technology, Kanpur, and his BT from Patna University in India – all in Mechanical Engineering. Dr. Prasad’s research interests include thermofluid sciences, energy systems, electronic materials, and micro-electronics. He has published over 200 refereed articles and edited/co-edited several books. Dr. Prasad is an elected Fellow of the American Society of Mechanical Engineers (ASME). He has received many special recognitions such as the Educator of the Year (2007) award from HENAAC and the LACCEI Medal from the Latin American and Caribbean Consortium of Engineering Institutions (LACCEI).

**Maria Cinta Pujol**

Universitat Rovira i Virgili
Department of Physics
and Crystallography of Materials
and Nanomaterials (FiCMA-FiCNA)
Tarragona, Spain
mariacinta.pujol@urv.cat

Chapter [C.21](#)

M.C. Pujol received the PhD in Chemistry from University Rovira i Virgili (2001) for work on the growth and characterization of lanthanide doped monoclinic double tungstates. Since 2004 she belongs to the group FiCMA (Physics and Crystallography of Materials). She is focussed on the growth of bulk and nanocrystals of lanthanide doped materials, and their crystal-physical and spectroscopic characterization.

Balaji Raghothamachar

Stony Brook University
Department of Materials Science
and Engineering
Stony Brook, NY, USA
braghoth@notes.cc.sunysb.edu

Chapters [D.23](#), [G.42](#)

Balaji Raghothamachar (Stony Brook University, PhD 2001) is Research Professor at the Department of Materials Science & Engineering, Stony Brook University and leading scientist for x-ray topography at the National Synchrotron Light Source (NSLS), Brookhaven National Laboratory, where he is involved in materials science engineering strategic planning for NSLS and NSLS-II. Research activities include x-ray topography, bulk and nanocrystal growth of semiconductor materials, high resolution x-ray diffraction and electron microscopy. He is an active member of MRS and AACG.

Michael Roth

The Hebrew University of Jerusalem
Department of Applied Physics
Jerusalem, Israel
mroth@vms.huji.ac.il

Chapter [C.20](#)

Michael Roth received the MSc degree in Physics from the University of Latvia (Riga, 1969) and the PhD degree in Physics from the Hebrew University of Jerusalem (1977). He joined the Hebrew University of Jerusalem as a faculty staff member in 1982 and is a Professor of Applied Physics there. His research interests include crystal physics, crystal growth, defect structure and properties of electronic materials. He is the President of the Israel Association for Crystal Growth and an Associate Editor of the Journal of Crystal Growth.

**Peter Rudolph**

Chapter A.6

Leibniz Institute for Crystal Growth
Technology Development
Berlin, Germany
rudolph@ikz-berlin.de

Professor Peter Rudolph is employed at the Leibniz Institute for Crystal Growth. He obtained the PhD in Solid State Physics from the Technical University of Lvov in 1972 and the Professor position at the Humboldt University of Berlin in 1985. From 1993-1994 he was Guest Professor at the Tohoku University in Sendai. His research includes all aspects of crystal growth. He is associate editor of J. Crystal Growth, president of the German Society of Crystal Growth and member of the IOCG executive committee. He received innovation prizes in 2001 and 2008.

**Akira Sakai**

Chapter E.34

Osaka University
Department of Systems Innovation
Osaka, Japan
sakai@ee.es.osaka-u.ac.jp

Professor Akira Sakai received the Master's degree in Engineering in 1986 and the doctorate in 1996 from Nagoya University. In 1986, he joined Fundamental Research Laboratory, NEC Corp. He became Associate Professor at the Graduate School of Engineering in Nagoya University in 1999 and Professor at the Graduate School of Engineering Science in Osaka University in 2007. His research interests include semiconductor epitaxial growth, defect and strain engineering, and characterization of materials on the micro- and nanometer scale. He is Member of the Japan Society of Applied Physics, the Electrochemical Society, and the Materials Research Society.

Yasuhiro Shiraki

Tokyo City University
Advanced Research Laboratories,
Musashi Institute of Technology
Tokyo, Japan
yshiraki@tcu.ac.jp

Chapter E.34

Yasuhiro Shiraki received the master's degree in applied physics in 1967 and the doctorate in 1975 from the University of Tokyo. In 1969, he joined the Central Research Laboratory, Hitachi, Ltd. He became Associate Professor at the Research Center for Advanced Science and Technology of the University of Tokyo in 1987 and Professor at the Department of Applied Physics in 1991. In 2004, he retired from the University of Tokyo and became Professor and Director of Advanced Research Laboratories, Musashi Institute of Technology. He currently serves as Vice-President of Tokyo City University which is the new name of the institute. He is Emeritus Professor of the University of Tokyo, Fellow of Institute of Physics, Fellow and Vice-President of the Japan Society of Applied Physics, and Member of Science Council of Japan.

Theo Siegrist

Florida State University
Department of Chemical
and Biomedical Engineering
Tallahassee, FL, USA
siegrist@eng.fsu.edu

Chapter D.25

Theo Siegrist is Professor in the Chemical and Biomedical Engineering Department at Florida State University. Previously, he was a Member of Technical Staff at Bell Laboratories, Alcatel-Lucent, where he was active in research on single-crystal organic semiconductors studying structure-property relationships in acene systems.

**Zlatko Sitar**

Chapter D.24

North Carolina State University
Materials Science and Engineering
Raleigh, NC, USA
sitar@ncsu.edu

Zlatko Sitar is Distinguished Kobe Steel Professor of Materials Science and Engineering at North Carolina State University. His research is concerned with crystal and thin-film growth and characterization of and device development in III-nitrides and carbon materials (GaN, AlN, InN, diamond, nanotubes), and study and formation of heterogeneous interfaces.

**Sivalingam Sivananthan**

Chapter E.32

University of Illinois at Chicago
Department of Physics
Chicago, IL, USA
siva@uic.edu; siva@epir.com

Dr. Sivananthan is Liberal Arts and Sciences Distinguished Professor of Physics, and Microphysics Laboratory Director at the University of Illinois at Chicago. He founded and is CEO of EPIR Technologies, Inc. and Sivananthan Laboratories, Inc. He pioneered the MBE growth of CdTe/Si and of HgCdTe on CdZnTe and CdTe/Si. His other primary interest is II–VI high-efficiency single-crystal multijunction solar cells.

Mikhail D. Strikovski

Chapter E.35

Neocera LLC
Beltsville, MD, USA
strikovski@neocera.com

Mikhail D. Strikovski is Senior Scientist at Neocera since 2000. He received his PhD from the Institute of Applied Physics, Russia (1985), and worked at the Texas Center for Superconductivity from 1996 to 2000. His main interests are physics and applications of plasma fluxes generated by pulsed-laser and electron beams. He is active in design of a variety of instrumentation for the pulsed plasma thin-film deposition technology.

Xun Sun

Chapter C.22

Shandong University
Institute of Crystal Materials
Jinan, China
sunxun@icm.sdu.edu.cn

Xun Sun is a Professor in the Institute of Crystal Materials, Shandong University, China. He received his PhD in Materials Science in 2002 from Shandong University. Dr. Sun's current research interests are functional crystal materials, especially the growth and properties of KDP (DKDP) crystals.

Ichiro Sunagawa

Chapter A.5

University Tohoku University (Emeritus)
Tokyo, Japan
i.sunagawa@nifty.com

Professor Ichiro Sunagawa graduated from Tohoku University in 1947 and received his DSc in 1957 and a Doc. Honoris Causa (France) in 1982. From 1948 to 1971 he was a mineralogist in the Geological Survey of Japan (GSJ) of the Agency of Industrial Science and Technology (old AIST) now National Institute of Advanced Industrial Science and Technology (new AIST). From 1971 to 1988 he was Professor of Mineralogy at Tohoku University, and from 1989 to 2007 Principal of the Yamanashi Institute of Gemmology and Jewellery Arts. His main interests are crystal growth fundamentals, mineralogy, and gemmology. He published many books and papers on these topics.

Xu-Tang Tao

Chapter C.22

Shandong University
State Key Laboratory of Crystal Materials
Jinan, China
txt@sdu.edu.cn

Xu-Tang Tao is a Professor of Functional Materials at the Institute of Crystal Materials and the State Key Laboratory of Crystal Materials, Shandong University. His research interests include organic and organic-inorganic hybrid photonic materials, laser and nonlinear optical crystal materials. He has published over 160 original papers and obtained several honors due to his studies.

Vitali A. Tatartchenko

Chapter B.16

Puteaux, France
vitali.tatartchenko@orange.fr

Vitali Tatartchenko graduated as an Engineer – Physicist from Leningrad Polytechnic University, received his PhD degree in 1970, Doctor of Sciences degree in 1977, and Professor rank in 1985. At famous institutions of the Soviet Union, Italy, Bulgaria, USA and France, he has had 50 years of unique experience of activity in all aspects of crystal growth: theory, experiments, installation design, and industrial technologies development. Dozens of his pupils have been active scientists in the field of crystal growth.

Filip Tuomisto

Helsinki University of Technology
Department of Applied Physics
Espoo, TKK, Finland
filip.tuomisto@tkk.fi

Chapter G.46

Filip Tuomisto received his Doctor of Science in Technology from the Department of Engineering Physics and Mathematics, Helsinki University of Technology (TKK) in 2005. He is currently an Academy Research Fellow at TKK, where he leads the positron research group. His research interests include physics of positrons in matter, defect spectroscopy of semiconductors and metals, and semiconductor optoelectronics.

Anna Vedda

University of Milano-Bicocca
Department of Materials Science
Milano, Italy
anna.vedda@unimib.it

Chapter H.50

Anna Vedda received the Laurea degree in Physics from the University of Milano in 1981, and she is currently Associate Professor at the University of Milano-Bicocca. Her principal fields of interest include the optical and structural properties of scintillating crystals and glasses for medical and high-energy physics applications, materials for radiation dosimetry, and insulating layers for microelectronics devices.

Lu-Min Wang

University of Michigan
Department of Nuclear Engineering
and Radiological Sciences
Ann Arbor, MI, USA
lmwang@umich.edu

Chapter G.44

Professor Lu-Min Wang has a Diploma in Metallic Materials Engineering from Beijing Polytechnic University (1982), an MS and holds a PhD in Materials Science, University of Wisconsin-Madison (1984, 1988). His primary research interests involve transmission electron microscopy (TEM) studies of microstructure evolution of solids during irradiation of energetic particles and particle beam modification of materials for engineering applications. He is seeking for a better understanding and control of the irradiation induced microstructure evolution. Lumin also has a strong interest in understanding the leaching processes of nuclear waste forms by cross-sectional TEM analysis. His most recent research effort focuses on ion beam modification of materials and irradiation induced nanostructures.

Sheng-Lai Wang

Shandong University
Institute of Crystal Materials,
State Key Laboratory of Crystal Materials
Jinan, Shandong, China
slwang@icm.sdu.edu.cn

Chapter C.22

Sheng-Lai Wang received the MS degree in Physics and the PhD degree in Materials Science from Shandong University in 1992 and 2000, respectively. Since 2005, he has been Professor at the Institute of Crystal Material (ICM) and The State Key Laboratory of Crystal Materials, Shandong University. His research interests are functional and ceramic materials mainly in KDP type crystal growth and related functional studies.

Shixin Wang

Micron Technology Inc.
TEM Laboratory
Boise, ID, USA
shixinwang@micron.com

Chapter G.44

Shixin Wang is a Senior Engineer at Micron Technology, Inc. He received his PhD degree from the University of New Mexico in 1997 and BS degree at Beijing Polytechnic University in 1986. His research interests are in radiation effects, electron optics, transmission electron microscopy, electron energy loss, and electron tomography.

Jan L. Weyher

Polish Academy of Sciences Warsaw
Institute of High Pressure Physics
Warsaw, Poland
weyher@unipress.waw.pl

Chapter G.43

Jan Weyher graduated as Mechanical Engineer and obtained MSc degree at Warsaw Technical University and PhD degree at Military Academy of Technology in Warsaw. He received DSc (habilitation) at University of Montpellier. His research activities are focused on studying defects in semiconductors, especially compound materials (GaAs, InP, GaN, SiC) using selective etching and complementary methods.

Jun Xu

Chinese Academy of Sciences
Shanghai Institute of Ceramics
Shanghai, China
xujun@mail.shcnc.ac.cn

Chapter [B.15](#)

Dr. Jun Xu is a Professor of Materials Science and Condensed Physics and research project leader at the Shanghai Institute of Ceramics, the Chinese Academy of Sciences (SIC,CAS). He has developed on optical single crystals, especially laser and opto-electronic functional crystals for more than 20 years. He was the winner of “China Youth Science and Technology Innovation Award”, awarded by All-China Youth Federation. He was also the winner of National Science Fund for Distinguished Young Scholars in 2005.

Hui Zhang

Tsinghua University
Department of Engineering Physics
Beijing, China
zhhui@tsinghua.edu.cn

Chapter [F.37](#)

Dr. Hui Zhang is a Professor of Engineering Physics at the Center for Public Safety Research at Tsinghua University in China. He received his PhD degree in Polytechnic University at Brooklyn in 1994 and worked as assistant professor and then an Associate Professor at the State University of New York at Stony Brook. His research interests include thermal system design, process modeling, computational fluid mechanics, and disaster modeling and mitigation.

Lili Zheng

Tsinghua University
School of Aerospace
Beijing, China
zhenglili@tsinghua.edu.cn

Chapter [F.37](#)

Dr. Lili Zheng is a Professor of Aerospace at Tsinghua University in China. She received her PhD degree in Cambridge University in 1994 and worked as Assistant Professor and then an Associate Professor at the State University of New York at Stony Brook. Her research interests include physically based modeling, engineering thermophysics, process control, and animation.

Mary E. Zvanut

University of Alabama at Birmingham
Department of Physics
Birmingham, AL, USA
mezvanut@uab.edu

Chapter [G.45](#)

Dr. Zvanut received her PhD in Physics from Lehigh University and studied transport at University of North Carolina and electronic materials at NRL. Dr. Zvanut joined the Physics Department at University of Alabama at Birmingham in September, 1992, and spent a sabbatical studying Si SiC at Wright Patterson AFB. Recent work focuses on the interactions of point defects in SrTiO₃ and the effect of oxidation and graphitization of SiC.

Zbigniew R. Zytkeiwicz

Polish Academy of Sciences
Institute of Physics
Warszawa, Poland
zytkie@ifpan.edu.pl

Chapter [E.30](#)

Zbigniew R. Zytkeiwicz received his PhD degree and then habilitation in Physics from the Institute of Physics of the Polish Academy of Sciences (IP PAS) in Warsaw. He is currently Professor at the IP PAS. His research interests include all aspects of physics and technology of epitaxial growth and defect engineering in semiconductor heteroepitaxial structures.

Detailed Contents

List of Abbreviations	XXXI
------------------------------------	------

Part A Fundamentals of Crystal Growth and Defect Formation

1 Crystal Growth Techniques and Characterization: An Overview

Govindhan Dhanaraj, Kullaiah Byrappa, Vishwanath (Vish) Prasad,

<i>Michael Dudley</i>	3
1.1 Historical Developments	3
1.2 Theories of Crystal Growth	4
1.2.1 Surface Energy Theory	5
1.2.2 Diffusion Theory	5
1.2.3 Adsorption Layer Theory	6
1.2.4 Screw Dislocation Theory	6
1.3 Crystal Growth Techniques	6
1.3.1 Solid Growth	7
1.3.2 Solution Growth	8
1.3.3 Crystal Growth from Melt	9
1.3.4 Vapor-Phase Growth	10
1.4 Crystal Defects and Characterization	11
1.4.1 Defects in Crystals	11
1.4.2 Observation of Crystal Defects	12
References	15

2 Nucleation at Surfaces

<i>Ivan V. Markov</i>	17
2.1 Equilibrium Crystal-Ambient Phase	18
2.1.1 Equilibrium of Infinitely Large Phases	18
2.1.2 Equilibrium of Small Crystal with the Ambient Phase	20
2.1.3 Equilibrium Shape of Crystals	22
2.2 Work for Nucleus Formation	24
2.2.1 General Definition	24
2.2.2 Formation of 3-D Nuclei on Unlike Substrates	25
2.2.3 Work of Formation of 2-D Crystalline Nuclei on Unlike and Like Substrates	27
2.3 Rate of Nucleation	28
2.3.1 General Formulation	28
2.3.2 Rate of Nucleation on Single-Crystal Surfaces	30
2.3.3 Equilibrium Size Distribution of Clusters	31
2.3.4 Rate of Nucleation	32
2.4 Saturation Nucleus Density	35
2.5 Second-Layer Nucleation in Homoepitaxy	38

2.6 Mechanism of Clustering in Heteroepitaxy 43

2.7 Effect of Surfactants on Nucleation 45

2.8 Conclusions and Outlook 48
